Problem Set 3

HOPS and Data Structures

Issued: Tuesday, September 17, 1996

Due: Friday, September 27, in recitation.

Tutorial preparation for: Week of September 23.

Reading Assignment: Sections 2.1 and 2.2 of *SCIP.*

1. Tutorial exercises

Tutorial Exercise 1 Give combinations of `car`s and `cdr`s that will pick 4 from each of the following lists:

```
(7 6 5 4 3 2 1)

((7) (6 5 4) (3 2) 1)

(7 (6 (5 (4 (3 (2 (1)))))))

(7 ((6 5 ((4)) 3) 2) 1)
```

Tutorial Exercise 2 Suppose we define `x` and `y` to be the two lists:

```
(define x (list 3 1 5))
(define y (list 2 4))
```

What result is printed by the interpreter in response to evaluating each of the following expressions:

```
(cons x y)

(list x y)

(append x y)
```

Tutorial Exercise 3 Prepare the following exercises for discussion in tutorial: 2.17, 2.21, 2.22 and 2.23 of `SICP`.

2. Laboratory Assignment: The Prisoner's Dilemma

The Prisoner's Dilemma: A Fable

In the mid-1920's, the Nebraska State Police achieved what may still be their finest moment. After a 400-mile car chase over dirt roads and through corn fields, they finally caught up with the notorious bank robbers Bunny and Clod. The two criminals were brought back to the police station in Omaha for further interrogation.

Bunny and Clod were questioned in separate rooms, and each was offered the same deal by the police. The deal went as follows (since both are the same, we need only describe the version presented to Bunny):

"Bunny, here's the offer that we are making to both you and Clod. If you both hold out on us, and don't confess to bank robbery, then we admit that we don't have enough proof to convict you. However, we *will* be able to jail you both for one year, for reckless driving and endangerment of corn. If you turn state's witness and help us convict Clod (assuming he doesn't confess), then you will go free, and Clod will get twenty years in prison. On the other hand, if you don't confess and Clod does, then *he* will go free and *you* will get twenty years."

"What happens if both Clod and I confess?" asked Bunny.

"Then you both get ten years," responded the police.

Bunny, who had been a math major at Cal Tech before turning to crime, reasoned this way: "Suppose Clod intends to confess. Then if I don't confess, I'll get twenty years, but if I do confess, I'll only get ten years. On the other hand, suppose Clod intends to hold out on the cops. Then if I don't confess, I'll go to jail for a year, but if I do confess, I'll go free. So no matter what Clod intends to do, I am better off confessing than holding out. So I'd better confess."

Naturally, Clod employed the very same reasoning. Both criminals confessed, and both went to jail for ten years.[1] The police, of course, were triumphant, since the criminals would have been free in a year had both remained silent.

The Prisoner's Dilemma

The Bunny and Clod story is an example of a situation known in mathematical game theory as the "prisoner's dilemma". A prisoner's dilemma always involves two "game players", and each has a choice between "cooperating" and "defecting." If the two players cooperate, they each do moderately well; if they both defect, they each do moderately poorly. If one player cooperates and the other defects, then the defector does extremely well and the cooperator does extremely poorly. (In the case of the Bunny and Clod story, "cooperating" means cooperating with one's partner – i.e.

[1] Well, actually they didn't go to jail. When they were in court, and heard that they had both turned state's witness, they strangled each other. But that's another story.

holding out on the police – and "defecting" means confessing to bank robbery.) Before formalizing the prisoner's dilemma situation, we need to introduce some basic game theory notation.

A Crash Course in Game Theory

In game theory, a *two-person binary-choice game* is represented by a two-by-two matrix. Here is a hypothetical game matrix.

	B cooperates	B defects
A cooperates	A gets 5 B gets 5	A gets 2 B gets 3
A defects	A gets 3 B gets 2	A gets 1 B gets1

The two players in this case are called **A** and **B**, and the choices are called "cooperate" and "defect." Players **A** and **B** can play a single game by separately (and secretly) choosing either to cooperate or to defect. Once each player has made a choice, he announces it to the other player; and the two then look up their respective scores in the game matrix. Each entry in the matrix is a pair of numbers indicating a score for each player, depending on their choices. Thus, in the example above, if Player **A** chooses to cooperate while Player **B** defects, then **A** gets 2 points and **B** gets 3 points. If both players defect, they each get 1 point. Note, by the way, that the game matrix is a matter of public knowledge; for instance, Player **A** knows before the game even starts that if he and **B** both choose to defect, they will each get 1 point.

In an *iterated game*, the two players play repeatedly; thus after finishing one game, **A** and **B** may play another. (Admittedly, there is a little confusion in the terminology here; you can think of each individual game as a single "round" of the larger, iterated game.) There are a number of ways in which iterated games may be played; in the simplest situation, **A** and **B** play for some fixed number of rounds (say 200), and before each round, they are able to look at the record of all previous rounds. For instance, before playing the tenth round of their iterated game, both **A** and **B** are able to study the results of the previous nine rounds.

An Analysis of a Simple Game Matrix

The game depicted by the matrix above is a particularly easy one to analyze. Let's examine the situation from Player **A**'s point of view (Player **B**'s point of view is identical):

"Suppose **B** cooperates. Then I do better by cooperating myself (I receive five points instead of three). On the other hand, suppose **B** defects. I still do better by cooperating (since I get two points instead of one). So no matter what **B** does, I am better off cooperating."

Player **B** will, of course, reason the same way, and both will choose to cooperate. In the terminology of game theory, both **A** and **B** have a *dominant* choice – i.e., a choice that gives a preferred outcome no matter what the other player chooses to do. The matrix shown above, by the way, does *not* represent a prisoner's dilemma situation, since when both players make their dominant choice, they also both achieve their highest personal scores. We'll see an example of a prisoner's dilemma game very shortly.

To re-cap: in any particular game using the above matrix, we would expect both players to cooperate; and in an iterated game, we would expect both players to cooperate repeatedly, on every round.

The Prisoner's Dilemma Game Matrix

Now consider the following game matrix:

	B cooperates	B defects
A cooperates	A gets 3 B gets 3	A gets 0 B gets 5
A defects	A gets 5 B gets 0	A gets 1 B gets1

In this case, Players **A** and **B** both have a dominant choice – namely, defection. No matter what Player **B** does, Player **A** improves his own score by defecting, and vice versa.

However, there is something odd about this game. It seems as though the two players would benefit by choosing to cooperate. Instead of winning only one point each, they could win three points each. So the "rational" choice of mutual defection has a puzzling self-destructive flavor.

The second matrix is an example of a prisoner's dilemma game situation. Just to formalize the situation, let CC be the number of points won by each player when they both cooperate; let DD be the number of points won when both defect; let CD be the number of points won by the cooperating party when the other defects; and let DC be the number of points won by the defecting party when the other cooperates. Then the prisoner's dilemma situation is characterized by the following conditions:

$$DC > CC > DD > CD$$

$$CC > \frac{DC + CD}{2}$$

In the second game matrix, we have

$$DC = 5, \qquad CC = 3, \qquad DD = 1, \qquad CD = 0$$

so both conditions are met. In the Bunny and Clod story, by the way, you can verify that:

$$DC = 0, \qquad CC = -1, \qquad DD = -10, \qquad CD = -20$$

Again, these values satisfy the prisoner's dilemma conditions.

Axelrod's Tournament

In the late 1970's, political scientist Robert Axelrod held a computer tournament designed to investigate the prisoner's dilemma situation[2]. Contestants in the tournament submitted computer

[2]Actually, there were two tournaments. Their rules and results are described in Axelrod's book: *The Evolution of Cooperation*.

programs that would compete in an iterated prisoner's dilemma game of approximately two hundred rounds, using the second matrix above. Each contestant's program played five iterated games against each of the other programs submitted, and after all games had been played the scores were tallied.

The contestants in Axelrod's tournament included professors of political science, mathematics, computer science, and economics. The winning program – the program with the highest average score – was submitted by Anatol Rapoport, a professor of psychology at the University of Toronto. In this problem set, we will pursue Axelrod's investigations and make up our own Scheme programs to play the iterated prisoner's dilemma game.

As part of this problem set, we will be running a similar tournament, but now involving a three-person prisoner's dilemma.

Before we look at the two-player program, it is worth speculating on what possible strategies might be employed in the iterated prisoner's dilemma game. Here are some examples:

All-Defect – a program using the **all-defect** strategy simply defects on every round of every game.

Poor-Trusting-Fool – a program using the **poor-trusting-fool** strategy cooperates on every round of every game.

Random – this program cooperates or defects on a random basis.

Go-by-Majority – this program cooperates on the first round. On all subsequent rounds, **go-by-majority** examines the history of the other player's actions, counting the total number of defections and cooperations by the other player. If the other player's defections outnumber her cooperations, **go-by-majority** will defect; otherwise this strategy will cooperate.

Tit-for-Tat – this program cooperates on the first round, and then on every subsequent round it mimics the other player's previous move. Thus, if the other player cooperates (defects) on the nth round, then **tit-for-tat** will cooperate (defect) on the $(n-1)$st round.

All of these strategies are extremely simple. (Indeed, the first three do not even pay any attention to the other player; their responses are uninfluenced by the previous rounds of the game.) Nevertheless, simplicity is not necessarily a disadvantage. Rapoport's first-prize program employed the **tit-for-tat** strategy, and achieved the highest average score in a field of far more complicated programs.

The Two-Player Prisoner's Dilemma Program

A Scheme program for an iterated prisoner's dilemma game is shown at the end of this problem set. The procedure `play-loop` pits two players (or, to be more precise, two "strategies") against one another for approximately 100 games, then prints out the average of the scores for each of the two players.

Player strategies are represented as procedures. Each strategy takes two inputs – its own "history" (that is, a list of all its previous "plays", where for convenience we will use 1 to represent cooperate, and -1 to represent defect) and its opponent's "history". The strategy returns either the number 1 for "cooperate" or the number -1 for "defect".

At the beginning of an iterated game, each history is an empty list. As the game progresses, the histories grow (via `extend-history`) into lists of 1's and -1's. Note how each strategy must have

its *own* history as its first input. So in *play-loop-iter*, `strat0` has `history0` as its first input, and `strat1` has `history1` as its first input.

The values from the game matrix are stored in a list named `*game-association-list*`. This list is used to calculate the scores at the end of the iterated game.

Some sample strategies are given at the end of the program. `All-defect` and `poor-trusting-fool` are particularly simple; each returns a constant value regardless of the histories. `Random-strategy` also ignores the histories and chooses randomly between cooperation and defection. You should study `go-by-majority` and `tit-for-tat` to see that their behavior is consistent with the descriptions in the previous section.

Problem 1 To be able to test out the system, we need to complete a definition for `extract-entry`. This procedure's behavior is as follows: it takes as input a game, represented as a list of choices for each strategy (i.e., a 1 or a -1), and the game association list. Each entry in the game association list is a list itself, with a first element representing a list of game choices, and the second element representing a list of scores for each player. Thus `extract-entry` wants to search down the game association list trying to match its first argument against the first element of each entry in the game association list, one by one. When it succeeds, it returns that whole entry.

For example, we expect the following behavior:

```
(define test (make-game 1 -1))
;Value: (1 -1)

(extract-entry test *game-association-list*)
;Value: ((1 -1) (0 5))
```

Write the procedure `extract-entry`, and test it out using `*game-association-list*`. Turn in a copy of your procedure listing and some test examples.

Problem 2 (no write-up necessary) Use `play-loop` to play games among the five defined strategies. Notice how a strategy's performance varies sharply depending on its opponent. For example, `poor-trusting-fool` does quite well against `tit-for-tat` or against another `poor-trusting-fool`, but it loses badly to `all-defect`. Pay special attention to `tit-for-tat`. Notice how it never beats its opponent – but it never loses badly.

Problem 3 Games involving `go-by-majority` tend to be slower than other games. Why is that so? Use order-of-growth notation to explain your answer.

Alyssa P. Hacker, upon seeing the code for `go-by-majority`, suggested the following iterative version of the procedure:

```
(define (go-by-majority my-history other-history)
  (define (majority-loop cs ds hist)
    (cond ((empty-history? hist) (if (> ds cs) -1 1))
          ((= (most-recent-play hist) 1)
           (majority-loop (+ 1 cs) ds (rest-of-plays hist)))
          (else
           (majority-loop cs (+ 1 ds) (rest-of-plays hist)))))
 (majority-loop 0 0 other-history))
```

Compare this procedure with the original version. Do the orders of growth (in time) for the two procedures differ? Is the newer version faster?

Problem 4 Write a new strategy `tit-for-two-tats`. The strategy should always cooperate unless the opponent defected on both of the previous two rounds. (Looked at another way: `tit-for-two-tats` should cooperate if the opponent cooperated on either of the previous two rounds.) Play `tit-for-two-tats` against other strategies.

Problem 5 Write a procedure `make-tit-for-n-tats`. This procedure should take a number as input and return the appropriate `tit-for-tat`-like strategy. For example, `(make-tit-for-n-tats 2)` should return a strategy equivalent to `tit-for-two-tats`.

Problem 6 Write a procedure `make-dual-strategy` which takes as input two strategies (say, `strat0` and `strat1`) and an integer (say `switch-point`). `Make-dual-strategy` should return a strategy which plays `strat0` for the first `switch-point` rounds in the iterated game, then switches to `strat1` for the remaining rounds.

Use `make-dual-strategy` to define a procedure `make-triple-strategy` which takes as input three strategies and two switch points.

Problem 7 Write a procedure `niceify`, which takes as input a strategy (say `strat`) and a number between 0 and 1 (call it `niceness-factor`). The `niceify` procedure should return a strategy that plays the same as `strat` except: when `strat` defects, the new strategy should have a `niceness-factor` chance of cooperating. (If `niceness-factor` is 0, the return strategy is exactly the same as `strat`; if `niceness-factor` is 1, the returned strategy is the same as `poor-trusting-fool`.)

Use `niceify` with a low value for `niceness-factor` – say, 0.1 – to create two new strategies: `slightly-nice-all-defect` and `slightly-nice-tit-for-tat`.

The Three-Player Prisoner's Dilemma

So far, all of our prisoner's dilemma examples have involved two players (and, indeed, most game-theory research on the prisoner's dilemma has focused on two-player games). But it is possible to create a prisoner's dilemma game involve three – or even more – players.

Strategies from the two-player game do not necessarily extend to a three-person game in a natural way. For example, what does `tit-for-tat` mean? Should the player defect if *either* of the opponents defected on the previous round? Or only if *both* opponents defected? And are either of these strategies nearly as effective in the three-player game as `tit-for-tat` is in the two-player game?

Before we analyze the three-player game more closely, we must introduce some notation for representing the payoffs. We use a notation similar to that used for the two-player game. For example, we let DCC represent the payoff to a defecting player if both opponents cooperate. Note that the first position represents the player under consideration. The second and third positions represent the opponents.

Another example: CCD represents the payoff to a cooperating player if one opponent cooperates and the other opponent defects. Since we assume a symmetric game matrix, CCD could be written as CDC. The choice is arbitrary.

Now we are ready to discuss the payoffs for the three-player game. We impose three rules:[3]

1) Defection should be the dominant choice for each player. In other words, it should always be better for a player to defect, regardless of what the opponents do. This rule gives three constraints:

$$DCC > CCC$$

$$DDD > CDD$$

$$DCD > CCD$$

2) A player should always be better off if more of his opponents choose to cooperate. This rule gives:

$$DCC > DCD > DDD$$

$$CCC > CCD > CDD$$

3) If one player's choice is fixed, the other two players should be left in a two-player prisoner's dilemma. This rule gives the following constraints:

$$CCD > DDD$$

$$CCC > DCD$$

$$CCD > \frac{CDD + DCD}{2}$$

$$CCC > \frac{CCD + DCC}{2}$$

We can satisfy all of these constraints with the following payoffs:

$$CDD = 0, \qquad DDD = 1, \qquad CCD = 3, \qquad DCD = 5, \qquad CCC = 7, \qquad DCC = 9.$$

[3]Actually, there is no universal definition for the multi-player prisoner's dilemma. The constraints used here represent one possible version of the three-player prisoner's dilemma.

Problem 8 Revise the Scheme code for the two-player game to make a three-player iterated game. The program should take three strategies as input, keep track of three histories, and print out results for three players. You need to change only three procedures: `play-loop`, `print-out-results` and `get-scores` (although you may also have to change your definition of `extract-entry` if you did not write it in a general enough manner). You also need to change `*game-association-list*` as follows:

```
(define *game-association-list*
  '(((1 1 1) (7 7 7))
    ((1 1 -1) (3 3 9))
    ((1 -1 1) (3 9 3))
    ((-1 1 1) (9 3 3))
    ((1 -1 -1) (0 5 5))
    ((-1 1 -1) (5 0 5))
    ((-1 -1 1) (5 5 0))
    ((-1 -1 -1) (1 1 1))))
```

Problem 9 Write strategies `poor-trusting-fool-3`, `all-defect-3`, and `random-strategy-3` that will work in a three-player game. Try them out to make sure your code is working.

Write two new strategies: `tough-tit-for-tat` and `soft-tit-for-tat`. `Tough-tit-for-tat` should defect if *either* of the opponents defected on the previous round. `Soft-tit-for-tat` should defect only if `both` opponents defected on the previous round. Play some games using these two new strategies.

Problem 10 A natural idea in creating a prisoner's dilemma strategy is to try and deduce what kind of strategies the *other* players might be using. In this problem, we will implement a simple version of this idea.

First, we need a procedure that takes three histories as arguments: call them `hist-0`, `hist-1` and `hist-2`. The idea is that we wish to characterize the strategy of the player responsible for `hist-0`. To do this, we are going to build an intermediary data structure which keeps track of what player-0 did, correlated with what the other two players did, over the course of the three histories.

You should design and implement a data structure called a `history-summary`, with the following overall structure (see figure 1). The `history-summary` has three subpieces, one for the case where both player-1 and player-2 cooperated, one for when one of them cooperated and the other defected, and a third for when both of these players defected. For each piece, there is another data structure that keeps track of the number of times player-0 cooperated, the number of times she defected, and the total number of examples. You may find it convenient to think of this as a kind of tree structure. Thus, your first task is to design constructors and selectors to implement this multilevel abstraction.

Once you have designed your data abstraction, build a procedure that takes the three histories as arguments, and returns a `history-summary`. If we extract from this data structure the piece corresponding to `cooperate-cooperate`, this should give us all the information about what happened when player-1 and player-2 both cooperated. Thus, we should be able to extract from this piece the number of times player-0 cooperated and the number of times she defected.

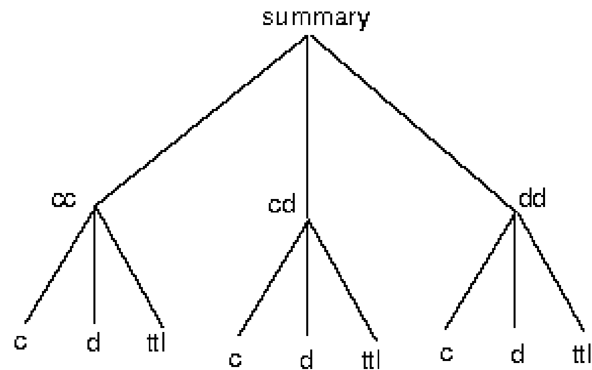

Figure 1: Example of the summary data structure, as a tree. The top level has three pieces, corresponding to the actions of the other players. The second level has three pieces, listing the number of times the player cooperated, defected and the total number of times the situation specified by the actions of the opponents occured.

Finally, using this data structure, we can build a new procedure that will return a list of three numbers: the probability that the `hist-0` player cooperates given that the other two players cooperated on the previous round, the probability that the `hist-0` player cooperates given that only one other player cooperated on the previous round, and the probability that the `hist-0` player cooperates given that both others defected on the previous round. To fill out some details in this picture, let's look at a couple of examples. We will call our procedure `get-probability-of-c`: here are a couple of sample calls.

```
(define summary (make-history-summary
                  (list  1  1  1 1)     ;hist-0
                  (list -1 -1 -1 1)     ;hist-1
                  (list -1 -1  1 1)))   ;hist-2
:Value: #t

(get-probability-of-c summary)
;Value: (1 1 1)

(define new-summary (make-history-summary
                       (list  1 1  1 -1 1)
                       (list -1 1 -1 -1 1)
                       (list -1 1  1  1 1)))
:Value: #t

(get-probability-of-c new-summary)
;Value: (0.5 1 ())
```

In the top example, the returned list indicates that the first player cooperates with probability 1 no matter what the other two players do. In the bottom example, the first player cooperates with probability 0.5 when the other two players cooperate; the first player cooperates with probability 1 when one of the other two players defects; and since we have no data regarding what happens when both of the other players defect, our procedure returns `()` for that case.

Write the `get-probability-of-c` procedure. Using this procedure, you should be able to write some predicate procedures that help in deciphering another player's strategy. For instance, here are two possibilities:

```
(define (test-entry index trial)
  (cond ((null? index)
          (if (null? trial) true false))
         ((null? trial) false)
         ((= (car index) (car trial))
          (test-entry (cdr index) (cdr trial)))
         (else false)))

(define (is-he-a-fool? hist0 hist1 hist2)
  (test-entry (list 1 1 1) (get-probability-of-c
                (make-history-summary hist0 hist1 hist2))))

(define (could-he-be-a-fool? hist0 hist1 hist2)
  (test-entry (list 1 1 1)
              (map (lambda (elt) (if (or (null? elt) (eq? elt 1)) 1 0))
                   (get-probability-of-c (make-history-summary hist0
                                                                hist1
                                                                hist2)))))
```

Note that we need to use `eq?` in `(eq? elt 1)` since `elt` could be a `'()` and thus `=` will not work unless you assume an evaluation order on the "or".

Use the `get-probability-of-c` procedure to write a predicate that tests whether another player is using the `soft-tit-for-tat` strategy from Problem 9. Also, write a new strategy named `dont-tolerate-fools`. This strategy should cooperate for the first ten rounds; on subsequent rounds it checks (on each round) to see whether the other players might both be playing `poor-trusting-fool`. If our strategy finds that both other players seem to be cooperating uniformly, it defects; otherwise, it cooperates.

Problem 11 Write a procedure `make-combined-strategies` which takes as input two *two-player* strategies and a "combining" procedure. `Make-combined-strategies` should return a *three-player* strategy that plays one of the two-player strategies against one of the opponents, and the other two-player strategy against the other opponent, then calls the "combining" procedure on the two two-player results. Here's an exmaple: this call to `make-combined-strategies` returns a strategy equivalent to `tough-tit-for-tat` in Problem 9.

```
(make-combined-strategies
  tit-for-tat tit-for-tat
  (lambda (r1 r2) (if (or (= r1 -1) (= r2 -1)) -1 1)))
```

The resulting strategy plays `tit-for-tat` against each opponent, and then calls the combining procedure on the two results. If either of the two two-player strategies has returned -1, then the three-player strategy will also return -1.

Here's another example. This call to `make-combined-strategies` returns a three-player strategy that plays `tit-for-tat` against one opponent, `go-by-majority` against another, and chooses randomly between the two results:

```
(make-combined-strategies
  tit-for-tat go-by-majority
  (lambda (r1 r2) (if (= (random 2) 0) r1 r2)))
```

Extra Credit: The Three-Player Prisoner's Dilemma Tournament

As described earlier, Axelrod held two computer tournaments to investigate the two-player prisoner's dilemma. We are going to hold a three-player tournament. You can participate by designing a strategy for the tournament. You might submit one of the strategies developed in the problem set, or develop a new one. The only restriction is that the strategy must work against any other legitimate entry. Any strategies that cause the tournament software to crash will be disqualified. If you wish to submit an entry strategy, you should:

- Send a copy of your procedure by email to your TA by the due date of the problem set (we will *not* accept entries submitted after the problem set is due). Include your name and a brief description of how the strategy works.
- The form of the submitted strategy should be a procedure that takes three arguments: the player's own history list and history lists for each of the other two players. The procedure should return either a 1 or a -1 for cooperate or defect.
- We reserve the right to disqualify any entries that violate the spirit of the prisoner's dilemma game (e.g., by "mutating" someone elses's history list).
- We *strongly* suggest that you try out your procedure in the lab (by using it as an argument to the three-person `play-loop` procedure) before submitting it.

The tournament will depend somewhat on the number of submitted entries. We will try to make the tournament as complete as possible (i.e., every strategy plays against every other pair). Each game will consist of approximately 100 rounds.
