Constrained Bimanual Planning with Analytic Inverse Kinematics

Thomas Cohn, Seiji Shaw, Max Simchowitz, and Russ Tedrake

Abstract—In order for a bimanual robot to manipulate an object that is held by both hands, it must construct motion plans such that the transformation between its end effectors remains fixed. This amounts to complicated nonlinear equality constraints in the configuration space, which are difficult for trajectory optimizers. In addition, the set of feasible configurations becomes a measure zero set, which presents a challenge to sampling-based motion planners. We leverage an analytic solution to the inverse kinematics problem to parametrize the configuration space, resulting in a lower-dimensional representation where the set of valid configurations has positive measure. We describe how to use this parametrization with existing motion planning algorithms, including sampling-based approaches, trajectory optimizers, and techniques that plan through convex inner-approximations of collision-free space.

I. INTRODUCTION

Enabling bimanual robots to execute coordinated actions with both arms is essential for achieving (super)human-like skill in automation and home contexts. There exists a variety of tasks that are only solvable when two arms manipulate in concert [1], such as carrying an unwieldy object, folding clothes, or assembling parts. In many manipulation tasks, one gripper can be used to provide fixture to the manipuland, while the other performs the desired action [2]; such tasks include opening a bottle, chopping vegetables, and tightening a bolt. Furthermore, some tools explicitly require two arms to use, such as hand mixers, rolling pins, and can openers.

To accomplish many of these desired tasks, the motion of the robot arms becomes subject to equality constraints imposed in task space. For example, when moving an object that is held by both hands, the robot must ensure that the transformation between the end effectors remains constant. Such task space constraints appear as complicated nonlinear equality constraints in configuration space, posing a major challenge to traditional motion planning algorithms.

In the existing literature, there are general techniques for handling task-space constraints in configuration-space planning. Sampling-based planners can project samples onto the constraint manifold [3] or use numerical continuation [4] to construct piecewise-linear approximations. Constraints can also be relaxed [5] or enforced directly with trajectory optimization [6]. In the case of certain bimanual planning problems, there is additional structure that is not exploited by these general methods. For certain classes of robot arms, analytic inverse kinematics (analytic IK) can be used to map an end-effector pose (along with additional parameters to resolve kinematic redundancy) to joint angles in closed form. Such solutions are specific to certain classes of robot arms, but are a powerful tool to be leveraged if available. Fortunately, analytic IK is available for many popular robot arms available today, including the KUKA iiwa. See Figure 1.

![Hardware setup for our experiments. The two arms must work together to move an object between the shelves, avoiding collisions and respecting the kinematic constraint.](Image)

If a robot must move an object that it is holding with both hands, we propose constructing a plan for one “controllable” arm, and then the other “subordinate” arm can be made to follow it via an analytic IK mapping. Configurations where the subordinate arm cannot reach the end-effector of the primary arm, or where doing so would require violating joint limits, are treated as obstacles. In this way, we parametrize the constraint manifold so that the feasible set has positive measure in the new planning space. Because we no longer have to consider the equality constraints, sampling-based planning algorithms can be applied without modification. We can also differentiate through the IK mapping, enabling the direct application of trajectory optimization approaches.

The remainder of this paper is organized as follows. First, we give an overview of the existing techniques used for constrained motion planning, and describe the available analytic IK solutions. Then, we present our parametrization of the constraint manifold for bimanual planning, and discuss its relevant geometric and topological properties. We describe the slight modifications which are necessary to adapt standard planning algorithms (including sampling-based planning and trajectory optimization) to operate in this framework. We then present a technique for generating...
convex sets in this new configuration space, such that every configuration within such a set is collision free and kinematically valid. These sets are essential for planning frameworks such as Graph of Convex Sets (GCS) [7], [8]. Finally, we present various experiments demonstrating the efficacy of these new techniques.

II. RELATED WORK

Constrained bimanual planning is an instance of the general problem of motion planning with task-space constraints, a well-studied problem in robotics. There has been extensive research into sampling-based approaches; these techniques fall under a number of broad categories:

- Relax the constraints (with real or simulated compliance) to give the feasible set nonzero volume [3], [9].
- Project samples to the constraint manifold [3], [10], [11].
- Construct piecewise-linear approximations of the constraint manifold [12], [13], [14], [15].
- Parametrize of the constraint manifold to eliminate constraints [16], [17].
- Build offline approximations of the constraint manifold, to simplify online planning [18], [19].

See the survey paper [20] for a more detailed summary.

Beyond sampling-based planning, standard nonconvex trajectory optimization approaches can handle arbitrary constraints, although they will generally only converge to a feasible solution with good initialization [20]. [6] used sequential convex programming on manifolds for nonconvex trajectory optimization. [21] greatly reduced constraint violations when computing trajectories on manifolds by enforcing collocation constraints in local coordinates.

Other approaches are designed specifically for the constraints that arise from robot kinematics. Inverse kinematics (IK) – computing robot joint angles so as to place the end effector at a given configuration – has been especially applicable. IK has long been used to sample constraint-satisfying configurations for bimanual robots, enabling the use of sampling-based planning algorithms [22], [23], [24], [25]. IK can be leveraged to find stable, collision-free configurations for a humanoid robot [26], to help a robot arm follow a prescribed task-space trajectory [27], and to satisfy the kinematic constraints that arise when manipulating articulated objects [28]. Differential IK techniques can be used to follow task space trajectories, while satisfying constraints [29], [30], [31].

A key part of our work is the use of a smooth IK mapping to parametrize the constraint manifold. Oftentimes, IK solutions are computed by solving a nonconvex mathematical program. The tools of algebraic geometry can be used to reformulate certain IK problems as systems of polynomial equations, which can be solved as eigenvalue problems [31], [32], [33]. However, neither of these methods yield closed-form IK solutions, nor do they guarantee smoothness. Smooth IK solutions for certain 6DoF arms can be produced by dividing the joints into two sets of three, and treating each of these as “virtual” spherical joints [34], §2.12.

IKFast [35] can be used to automatically construct analytic IK solutions for broad classes of robot arm kinematics, and is available as part of the OpenRAVE toolkit [36]. Some arms have specifically-designed geometric solutions, such as the Universal Robotics UR-5/UR-10 [37].

Robot arms with more than six degrees of freedom have kinematic redundancy – the arm can be moved while keeping its end effector fixed. This is called self-motion and is useful for avoiding obstacles and joint limits, but it implies that the forward kinematic mapping cannot be bijective. [38] computes a globally-consistent pseudoinverse (discarding the redundancy), but this artificially restricts the configuration space. Other approaches characterize the redundancy as a free parameter to be controlled in addition to the end-effector pose. [39] presents a strategy for treating specific joints in a 7DoF arm as free parameters, reducing the problem to that of a 6DoF arm. IKFast can discretize any additional joints. Similar to the sphere-sphere 6DoF arms, certain 7DoF arms have a sphere-revolute-sphere kinematic structure (similar to the human arm), leading to elegant geometric solutions [40], [41]. Specific geometric solutions are available for many common robot arms, including the KUKA iiwa [42], Franka Emika Panda [43], and the Barrett WAM [44].

Our parametrization can be combined with many planning algorithms to form a complete system. In this paper, we specifically examine the canonical sampling-based planners: Rapidly-Exploring Random Trees (RRTs) [45] and Probabilistic Roadmaps (PRMs) [46]. Our contributions can also be used with the many extensions to these techniques [47], [48], [49], [50], [51], [52], [53]. We also describe how to use standard kinematic trajectory optimization techniques [50], §7.2, [54], [55], [56]. Finally, we describe how to extend the IRIS-NP algorithm [57] for computing convex collision-free sets to use our parametrization of the configuration space; such sets can be planned across with the GCS planning framework [3]. (These sets can also be used with other “convex set planning algorithms” [58], [59], [60].)

III. METHODOLOGY

We introduce a bijective mapping between joint angles and end-effector pose for a single arm with analytic IK. We then use this mapping to parametrize the set of valid configurations for constrained bimanual manipulation. The
joint angles of one arm are treated as free variables for the parametrized configuration space, and the aforementioned mapping is used to determine the joint angles for the other arms (visualized in Figure 2). Finally, we explain the modifications needed to adapt existing planning algorithms to utilize this parametrization.

A. Topology of Inverse Kinematics

The topological and geometric properties of inverse kinematic mappings are a classic area of study in robotics \[61\], \[62\], \[63\]. For an arm with \( n \geq 6 \) revolute joints, the configuration space is \( C \subseteq \mathbb{T}^n \), where \( \mathbb{T}^n \) denotes the \( n \)-torus. The forward kinematic mapping \( f : C \to \text{SE}(3) \) computes the end-effector pose of the arm for a given choice of each joint angle. We define the reachable set \( X = \{ f(\theta) : \theta \in C \} \subseteq \text{SE}(3) \). To construct a homeomorphism between subsets of \( C \) and \( X \), we must restrict our domain of attention to avoid singular configurations, and augment \( X \) with additional degrees of freedom to match dimensions.

We give an overview of the terminology introduced in \[62\] for describing the global behavior of inverse kinematic mappings. A configuration for which the Jacobian of \( f \) is full-rank is called a regular point; otherwise, it is called a critical point. Because \( f \) is not injective, the preimage of a single end-effector pose may contain only critical points, only regular points, or some of both; it is respectively called a critical value, regular value, and coregular value. \( W \)-sheets are the connected components of regular values in \( X \) whose boundaries are the coregular values of \( f \). The connected components of the preimages of \( W \)-sheets are called \( C \)-bundles and are composed of regular points of \( C \). For a regular value \( x \in X \), we have

\[
f^{-1}(x) = \bigcup_{i=1}^{m} M_i(x), \tag{1}
\]

where the \( M_i(x) \) are self-motion manifolds of \( x \), so called because motion within them does not affect the end-effector pose. The label \( i \) is called the global configuration parameter, and a choice of \( \psi \in M_i(x) \) is called the redundancy parameter. According to \[62\], for robot arms in 3D space, the number of self-motion manifolds is at most 16; within a \( C \)-bundle, the self-motion manifolds are homotopic; and if the arm has only revolute joints, then the self-motion manifolds are diffeomorphic to \( \mathbb{T}^{n-6} \). (If \( n = 6 \), then the \( M_i \) are zero-dimensional, i.e., discrete points.) Examples of the continuous and discrete self motions for a 7DoF arm are shown in Figure 3.

The \( C \)-bundle/\( W \)-sheet machinery allows us to construct well-defined IK mappings. Let \( W_j \subseteq X \) be a \( W \)-sheet, and let \( x_0 \in W_j \). Then there is an smooth injection \( g_{i,j} : W_j \times M_i(x_0) \to C \). Since the self-motion manifolds are homotopic within a \( C \)-bundle, they are uniquely described in terms of their choice of \( C \)-bundle and \( W \)-sheet, so we use the shorthand \( M_{i,j} \) in place of \( M_i(x_0) \). If we let \( h_{i,j} \) map joint angles to their corresponding redundancy parameter, then \((f, h_{i,j}) \circ g_{i,j}\) is the identity mapping on \( W_j \times M_{i,j} \). Thus, with appropriate restrictions in domain and range, we have a bijection between the arm’s joint angles and the product of its end-effector pose and redundancy parameters. The set \( C_{i,j} \), defined as the image of \( g_{i,j} \), is the set of joint angles which can be handled by these mappings.

B. Parametrizing the Kinematically Constrained Space

Now, we turn our attention to the bimanual case. We use an additional subscript to denote which arm the sets and maps correspond to; for example, \( X_i \) is the reachable set of the “left” arm, and \( g_{i,j,R} \) denotes the inverse kinematic mapping for the “right” arm.

When a rigid object is held with both end effectors, a rigid transformation \( T \in \text{SE}(3) \) between them becomes fixed; we let \( \phi_T : X_L \to \text{SE}(3) \) take in an end-effector pose for the left arm (henceforth called the controlled arm), and output the target end-effector pose for the right arm (henceforth called the subordinate arm). We let \( X_T := \{(x, \phi_T(x)) : x \in X_L \} \subseteq X_L \times \text{SE}(3) \) denote the space of end-effector poses which are feasible for the controlled arm and for which the pose of subordinate end-effector respects transformation \( T \). Note that this latter pose may not be reachable for the subordinate arm, and a choice of redundancy parameter may require a violation of its joint limits. We treat both of these cases as abstract obstacles in the configuration space.

For the remainder of the paper, we fix the global configuration parameter \( i \) and choice of \( W \)-sheet \( j \) for the second arm. Let \( T \) be the desired end-effector transformation. We define a parametrized configuration space \( Q := C_L \times M_{i,j,R} \). \( q \in Q \) determines joint angles for both arms via the mapping

\[
\xi : (\theta_L, \psi_R) \mapsto (\theta_L, g_{i,j,R}(\phi_T(f_L(\theta_L)), \psi_R)). \tag{2}
\]

For more details on why we select this specific parametrization, see Section [V]. Let \( \theta_{\min} \) and \( \theta_{\max} \) be the lower and upper joint limits. A configuration \( (\theta_L, \psi_R) \) is valid if:

\[
\phi_T(f_L(\theta_L)) \in W_j, R \quad \text{(Respect reachability.)} \tag{3a}
\]

\[
\theta_{\min} \leq \xi(\theta_L, \psi_R) \leq \theta_{\max} \quad \text{(Respect joint limits.)} \tag{3b}
\]

We call the set of configurations satisfying these constraints \( Q_{\text{VALID}} \). For \( q \in Q \), if the robot is collision free for the joint angles \( \xi(q) \), we say \( q \in Q_{\text{FREE}} \).

C. Reformulating the Motion Planning Problem

Let \( s, t \in C_L \times C_R \) be the start and goal configurations. The constrained motion planning problem requires finding a...
path \( \gamma = (\gamma_L, \gamma_R) : [0, 1] \rightarrow C_L \times C_R \) by solving:

\[
\begin{align*}
\text{argmin } & \quad L(\gamma) \\
\text{s.t. } & \quad \gamma(t) \text{ collision free } \quad \forall t \in [0, 1] \quad (4a) \\
& \quad \phi_T(f_L(\gamma_L(t))) = f_R(\gamma_R(t)) \quad \forall t \in [0, 1] \quad (4b) \\
& \quad \gamma(0) = s, \quad \gamma(1) = t. \quad (4d)
\end{align*}
\]

(\( L \) denotes the arc length functional, but can be replaced with another cost.) The main challenge this formulation presents is the nonlinear equality constraint (4c), as this requires \( \gamma \) lie along a measure-zero set. Trajectory optimizers may struggle with (4c), and sampling-based planners must use one of the techniques described in Section II.

Our \textit{parametrized motion planning problem} is written in terms of a trajectory \( \bar{\gamma} : [0, 1] \rightarrow \mathcal{Q} \), with start \( \bar{s} \) and goal \( \bar{t} \) satisfying \( \xi(\bar{s}) = \bar{s} \) and \( \xi(\bar{t}) = \bar{t} \):

\[
\begin{align*}
\text{argmin } & \quad L(\xi \circ \bar{\gamma}) \\
\text{s.t. } & \quad (\xi \circ \bar{\gamma})(t) \text{ collision free } \quad \forall t \in [0, 1] \quad (5b) \\
& \quad \bar{\gamma}(t) \in \mathcal{Q}_{\text{VALID}} \quad \forall t \in [0, 1] \quad (5c) \\
& \quad \bar{\gamma}(0) = \bar{s}, \quad \bar{\gamma}(1) = \bar{t}. \quad (5d)
\end{align*}
\]

This formulation includes the implicit requirement that the entire planned trajectory be within a single \( \mathcal{C} \)-bundle, due to the restricted domain of \( \xi \). In Section IV we demonstrate that this theoretical limitation is not a major roadblock to our framework’s efficacy. A major advantage of parametrization methods is that by construction, the end-effector poses \( (f_L, f_R) \circ (\xi \circ \bar{\gamma})(t) \) are \textit{guaranteed} to be related by transformation \( T \). For other methodologies, the constraints are only satisfied at discrete points along the trajectory.

\section{D. Motion Planning with the Parametrization}

Constraint (5c) is a nonlinear inequality constraint, so feasible trajectories are constrained to lie in a positive volume set \( \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \). Thus, unconstrained motion planning algorithms can function with only slight modifications.

1) \textit{Sampling-Based Planning:} The changes required for sampling based planners can be summarized as treating points outside \( \mathcal{Q}_{\text{VALID}} \) as being in collision. Because \( \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \) has positive measure, rejection sampling can be used to draw valid samples. When connecting samples (as in the “Extend” procedure of an RRT or “Connect” procedure of a PRM), the frequency with which collisions are checked must be adjusted, since distance in the parametrized space \( \mathcal{Q} \) differs from distance in the full configuration space \( C_L \times C_R \). In particular, a small motion in \( \mathcal{Q} \) can lead to a relatively large motion in \( C_L \times C_R \), so collision checking must be done more frequently (or at a varying scale).

2) \textit{Trajectory Optimization:} Trajectory optimization in configuration space is already nonconvex, so implementing constraints (5b) and (5c) requires no algorithmic changes. As with sampling-based planning, collision avoidance (and other constraints applied to the full configuration space) must be enforced at a finer resolution.

\section{3) Graph of Convex Sets:} Let \( \mathcal{U} \subseteq \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \) be convex. Then the kinematic validity (and collision-free nature) of a linear path through \( \mathcal{U} \) is guaranteed if its endpoints are contained in \( \mathcal{U} \). Thus, the Graph of Convex Sets Planner (GCS) can function as expected with two small modifications. We minimize the arc length in the parametrized space \( L(\bar{\gamma}) \), as this objective provides a useful convex surrogate for the true (nonconvex) objective (5a). Also, for robust arms composed of revolute joints, the self-motion parameters are angle-valued, so one can either make cuts to the configuration space and treat it as Euclidean, or use the extension \textit{Graphs of Geodesically-Convex Sets} (GGCS) \cite{GGCS}. The product of the angle-valued self-motion parameters will be a circle or n-torus, both of which admit a flat metric \cite[p.345]{flatmetric}. If we plan across geodesically convex (g-convex) subsets of \( \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \), then the problem satisfies the conditions presented in Assumptions 1 and 2 of \cite{GGCS}. These assumptions guarantee that the resulting path will be kinematically valid and collision-free at all times.

\section{E. Constructing Convex Valid Sets}

To use (G)GCS, one must construct (g-)convex subsets of \( \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \). The IRIS-NP algorithm \cite{IRIS-NP} uses a counterexample search to find configurations in collision and constructs hyperplanes to separate the set from such configurations. IRIS-NP can support inequality constraints beyond collision-avoidance, but they must be inequalities. By running IRIS-NP through our parametrization, we avoid the equality constraints that would otherwise be present in our constrained bimanual manipulation problem. Given a hyperellipsoid \( \mathcal{E}(C, d) = \{ q : ||q - d||_C^2 \leq 1 \} \) (using the notation \( ||q - d||_C^2 = (q - d)^T C^T C (q - d) \), a halfspace intersection \( \mathcal{H}(A, b) = \{ q : Aq \leq b \} \), and a constraint set \( \mathcal{CS} \), the \textit{generalized counterexample search} program is

\[
\begin{align*}
\min & \quad ||q - d||_C^2 \\
\text{s.t. } & \quad Aq \leq b \quad (6b) \\
& \quad q \notin \mathcal{CS}. \quad (6c)
\end{align*}
\]

Given a bounding box \( \mathcal{H}_0(A_0, b_0) \), a hyperellipsoid \( \mathcal{E}(C, d) \) with \( d \in \mathcal{H}_0(A_0, b_0) \), and a list of configuration-space constraints \( \mathcal{CS}_1, \ldots, \mathcal{CS}_k \) to enforce, Algorithm \ref{alg} produces a halfspace intersection \( \mathcal{H}(A, b) \subseteq \mathcal{H}_0(A_0, b_0) \) such that every point in \( \mathcal{H}(A, b) \) satisfies the constraints.

We now describe the constraint sets \( \mathcal{CS} \) needed for Algorithm \ref{alg} to generate g-convex sets in \( \mathcal{Q}_{\text{VALID}} \cap \mathcal{Q}_{\text{FREE}} \), and how to encode (6c). For \( q = (\theta_L, \psi_R) \) (or \( q = (\theta_L, \psi_R, T) \) if the end effector transformation is allowed to vary), consider the auxiliary variable \( \theta_R \) denoting the joint angles of the subordinate arm, computed with \( (\theta_L, \theta_R) = \xi(q) \).

First, we require that any inverse trigonometric functions used in the analytic IK mapping \( g_{i,j,R} \) do not violate their domains. Although this constraint would be enforced by the later constraints, specifically handling this case first greatly improves the performance of the later counterexample searches. For example, \cite[Eq. 4]{IK} takes the \textit{arcocos} of an argument \( w \), so we encode (6c) as \( |w| \geq 1 + \epsilon \). When using
For a configuration $q$, we check the joint limits (3b), encoded for (6c) as
\[
\theta_{\text{max}} - \theta_{\text{min}} - \xi(q) \geq \epsilon.
\]

Finally, a configuration $q$ is said to be reachable if
\[
\phi_T(f_L(\theta_L)) = f_R(\theta_R).
\]
Although this is an equality constraint, the set of configurations satisfying the constraint has positive volume in the parametrized space, so Algorithm 1 can still be used to generate a convex inner-approximation. For reachability counterexamples [5a], we compute the squared Frobenius norm of the difference between desired and realized end-effector pose, encoding (6c) as
\[
||\phi_T(f_L(\theta_L)) - f_R(\theta_R)||^2 \geq \epsilon.
\]

These three constraints will ensure $H(A, b) \subseteq Q_{\text{VALID}}$. To also enforce $H(A, b) \subseteq Q_{\text{FREE}}$, we search for configurations $q$ such that the robot is in collision. We separately find counterexamples for each pair of collision bodies, using equation (2) of [57]. Note that this equation operates on the full configuration $(\theta_L, \theta_R)$, as obtained from the parametrized configuration with $\xi$. Because (6) is a nonlinear program, we solve it using SNOPT [66] with random initializations until a solution is obtained or a predefined number of consecutive failures is reached (and in that case, return infeasible).

We demonstrate our new constrained planning framework using a bimanual manipulation setup with two KUKA iiwa 7DoF arms. Interactive recordings of all trajectories are available online at https://cohnt.github.io/Bimanual-Web/. We use the analytic IK map presented in [42]. To evaluate the merits of our IK parametrization for constrained planning, we consider a task where the two arms must move an object.

TABLE II: Online planning time (in seconds) for each method with various start and goal configurations. Paths marked with an asterisk were not collision-free.

3a. IK-PRM. We use the multi-query PRM algorithm [46], initialized with nodes from multiple BiRRTs to ensure connectivity, as in [8 §C].

4a. IK-GCS. We use GCS-planner [8] with 19 regions, constructed from hand-selected seed points. For both the BiRRT and PRM plans, we use short-cutting to post-process the paths [69]. We solve the GCS problems with Mosek [70]. We compare these parametrized planners with constrained planning baselines.

1b. Constrained Trajectory Optimization. We solve [4] with kinematic trajectory optimization, using the IK-BirRT plan as the initial guess to compare with IK-Trajopt.

2b. Sampling-Based Planning. For sampling-based planners, we use the single-query Atlas-BirRT and multi-query Atlas-PRM algorithms [15], as implemented in the Open Motion Planning Library [11]. The atlas and PRM are initialized from multiple Atlas-BirRT runs.

We do not compare to any GCS baseline without IK, as the constraint manifold is inherently nonconvex; IK-GCS is the first proposal for extending GCS to this class of problems.

**Constraint Violations:** Because the baseline methods can only enforce the kinematic constraint at discrete points, the constraint violation can be significant between such points. The OMPL planners experienced a maximum constraint violation of 6.62 cm, and the trajectory optimization baseline experienced a maximum constraint violation of 3.22 cm. In comparison, our parametrization methods maintained all constraints within 0.001 cm. Plans from the trajectory optimization baseline also had slight collisions with obstacles.

**Path Length & Planning Time:** Across all methods, for various start and goal configurations, we compare path length in Table I and online planning time in Table II. We ran both BiRRT methods 10 times for each plan, and report the
This parametrization also enables the use of planners such as GCS, which previously could not be applied to configuration spaces with nonlinear equality constraints.

Other parametrizations for the constrained configuration space are symmetric, and may seem more natural:

1) Treating the end-effector configuration and redundancy parameters for both arms as the free variables, and using analytic IK for both arms.
2) Treating the first four joints of each arm as free variables, and solving IK for the remaining six joints as a virtual 6DoF arm whose middle link is represented by the object held by both end-effectors.

But these choices present other disadvantages.

For the first option, we would have to choose global configuration parameters for both arms; in the case of the KUKA iiwa, this involves 64 choices (instead of the 8 options for our parametrization). Also, the shortest paths for the end effector may lead to very inefficient paths in joint space – our parametrization can at least minimize the joint space distance for one arm. Finally, it requires planning over SO(3), which is not possible for GCS (see [64, Thm. 5]).

For the second option, the choice of end-effector transformation \( T \) determines the kinematic structure of the virtual arm, so different grasps would require different analytic IK solutions. Constructing such solutions would be time-consuming, and they may not always exist.

There are clear directions for future work. Enabling the planner to move between \( C \)-bundles would unlock a greater variety of arm motions, potentially allowing the selected planner to compute shorter paths. Another important future step is to explicitly consider singular configurations. The IK mapping used in this work is still defined at singular configurations, but nearby configurations may violate the subordinate arm joints limits or reachability constraints. This makes the IRIS region generation process implicitly avoid singular configurations, but the other planning methodologies may not detect infeasible configurations near singularities.
