Abstract. Erasure codes offer an efficient way to decrease storage and communication costs while implementing atomic memory service in asynchronous distributed storage systems. In this paper, we provide erasure-code-based algorithms having the additional ability to perform background repair of crashed nodes. A repair operation of a node in the crashed state is triggered externally, and is carried out by the concerned node via message exchanges with other active nodes in the system. Upon completion of repair, the node re-enters active state, and resumes participation in ongoing and future read, write, and repair operations. To guarantee liveness and atomicity simultaneously, existing works assume either the presence of nodes with stable storage, or presence of nodes that never crash during the execution. We demand neither of these; instead we consider a natural, yet practical network stability condition \( N_1 \) that only restricts the number of nodes in the crashed/repair state during broadcast of any message.

We present an erasure-code based algorithm \( \text{RADON}_C \) that is always live, and guarantees atomicity as long as condition \( N_1 \) holds. In situations when the number of concurrent writes is limited, \( \text{RADON}_C \) has significantly improved storage and communication cost over a replication-based algorithm \( \text{RADON}_R \), which also works under \( N_1 \). We further show how a slightly stronger network stability condition \( N_2 \) can be used to construct algorithms that never violate atomicity. The guarantee of atomicity comes at the expense of having an additional phase during the read and write operations.

1 Introduction

We consider the problem of designing algorithms for distributed storage systems (DSSs) that offer consistent access to stored data. Large scale DSSs are widely used by several industries, and also widely studied by academia for a variety of applications ranging from e-commerce to sequencing genomic-data. The most desirable form of consistency is atomicity, which in simple terms, gives the users of the data service the impression that the various concurrent read and write operations take place sequentially. Implementations of atomicity on an asynchronous system under message passing framework, in the presence of failures, is often challenging. Traditional implementations [1], [2] use replication of data as the mechanism of fault-tolerance; however they suffer from the problem of having high storage cost, and communication costs for read and write operations.

Erasure codes provide an efficient way to decrease storage and communication cost in atomicity implementations. An \([n, k]\) erasure code splits the value \( v \), say of size 1 unit into \( k \) elements, each of size \( \frac{1}{k} \) units, creates \( n \) coded elements, and stores one coded element per server. The size of each coded element is also \( \frac{1}{k} \) units. A class of erasure codes known as Maximum Distance Separable (MDS) codes have the property that value \( v \) can be reconstructed from any \( k \) out of these \( n \) coded elements. While it is known that usage of erasure codes in asynchronous decentralized storage systems do not offer all the advantages as in synchronous centralized systems [3], erasure code based algorithms like in [4], [5], [6], or [7] for implementing consistent memory service offer significant storage and communication cost savings over replication based algorithms, in many regimes of operation. For instance CASGC [4] improves the costs under the scenario when the number of writes concurrent with a read is known to be limited, whereas SODA [7] trades-off write cost in order to optimize storage cost, which is meaningful in systems with infrequent writes. Both CASGC and SODA are based on MDS codes.
In this work, we consider the additional important issue of repairing crashed nodes without disrupting the storage service. Failure of storage nodes is a norm rather than an exception in large scale DSSs today, primarily because of the usage of commodity hardware for affordability and scalability reasons. Replication based algorithms in [1], [2] and erasure-code based algorithms in [4], [6], or [7] do not consider repair of crashed nodes; instead assume that a crashed node remains so for the rest of the execution. Algorithms in [5], [8] consider background repair of crashed nodes; however they assume either the presence of nodes having stable storage, whose content is unaffected by crashes, or presence of a subset of nodes that never crash during the entire execution. We relax both these assumptions in this work. In our model, any one of the storage nodes can crash; further, we assume that a crashed node loses all its data, both volatile as well as stable storage. A repair operation of a node in the crashed state is triggered externally, and is carried out by the concerned node via message exchanges with other active nodes in the system. Upon completion of repair, the node (with the same id) re-enters active state, and resumes participation in ongoing and future read, write, and repair operations.

It is natural to expect a restriction on the number of crash and repair operations in relation to the read and write operations; the authors of [8] show an impossibility result in this direction, for guaranteeing liveness and atomicity, simultaneously. We formulate network stability conditions $N_1$ and $N_2$, which can be used to limit the number of crash and repairs operations overlapping with a client operation. These conditions are algorithm independent, and most likely to be satisfied in any practical storage network. At a high level, the condition $N_1$ restricts the set of servers that can be in the crashed or repair state any time a process (client or server) pings all the $n$ servers with corresponding messages. Condition $N_2$ is slightly stronger than $N_1$, and restricts the set of servers that can be in the crashed or repair state if the process wants to ping-pong a fraction of the servers. In a ping-pong, it is expected that the servers which receive a message also respond back to the sender of the message.

1.1 Summary of Our Contributions

We first present an impossibility result for an asynchronous DSS allowing background repair of crashed nodes, where there is no restriction on the number of crash and repair operations that occur during a client operation. We show that it is impossible to simultaneously achieve liveness and atomicity in such a system, even if all the crash and repair operations occur sequentially during the execution (i.e., at most one node remains in the crash or repair state at any point during the execution).

We then consider the problem of erasure-code based algorithm design under the network stability condition $N_1$. We present the algorithm in two stages. First we present a replication-based algorithm $RADO_{NR}$, which performs background-repair, and guarantees atomicity and liveness of operations under $N_1$, if more than $3/4$th of all servers remain active during any ping operation. The write and read phases are almost identical to those of the ABD algorithm [1], except that during a write we expect responses from more than $3/4$th of all the servers, while in ABD responses are expected only from a majority of servers. A repair operation in $RADO_{NR}$ is simply a read operation initiated by the concerned server. Thus the algorithm itself is simple; however, the proof of atomicity gets complicated because of the fact that a repair operation can potentially restore the contents of a node to a version that is older than what was present before the crash. We show how the network stability condition can be used to prove atomicity, and this proof is the key takeaway from $RADO_{NR}$ towards constructing the erasure-code based algorithm.
Our erasure-code based algorithm $RADON_C$ uses $[n, k]$ MDS codes, and is a natural adaptation of $RADON_R$ for the usage of codes. A key challenge while using erasure codes is ensuring liveness of read operations, in the presence of concurrent write operations. Various techniques are known in literature to handle this challenge; for instance, [5] assumes synchronous write phases, [6] limits the number of writes concurrent with a read, while [7] uses an $O(n^2)$ write protocol to guarantee liveness of reads. In this work, like in [6], we make the assumption that the number of write operations concurrent with any read operation is limited by a parameter $\delta$, which is known a priori. However, the usage of the concurrency bound differs from that of the CASGC algorithm in [6]; for instance, CASGC has three rounds for write operations, while $RADON_C$ uses only two rounds. In $RADON_C$, each server maintains a list of up to $\delta + 1$ coded elements, corresponding to the latest $\delta + 1$ versions received as a result of the various write operations. In comparison with $RADON_R$ where a writer expects responses from more than $3/4$ of all servers, a write operation in $RADON_C$ expects responses from more than $3\delta + n$ servers. During a read operation, the client reads the lists from more than $\frac{n + k}{2}$ nodes before decoding the value $v$. Like in $RADON_R$, a repair operation in $RADON_C$ is essentially a read operation by the concerned node; however this time the concerned node creates a list (instead of just one version) by decoding as many possible versions that it can from the $\lceil \frac{n + k}{2} \rceil$ responses. Liveness and atomicity of operations are proved under network stability condition $N1$, if more than $3\delta + n$ servers remain active during any ping operation. $RADON_C$ has substantially improved storage and communication costs than $RADON_R$, when the concurrency bound $\delta$ is limited; see Table 1 for a comparison.

In both $RADON_R$ and $RADON_C$, violation of the network stability condition $N1$ can result in executions that are not atomic, which might not be preferable in certain applications. The choice of consistency over liveness, or vice versa, is the subject matter of a wide range of discussions and perspectives among system designers and software engineers. For example, BigTable, a DSS by Google, prefers safety over liveness [9], whereas, Amazon’s Dynamo does not compromise liveness but settles for eventual consistency [10]. Our third algorithm $RADON_R^{(S)}$, which is replication-based, is designed to guarantee atomicity during every execution. Liveness is guaranteed under the slightly more stringent condition of $N2$, with more than $3/4$ of all servers remaining active during any ping-pong operation. The guarantee of atomicity of every execution also needs extra phases for read and write operations, when compared to $RADON_R$. The design of an erasure-coded version of $RADON_R^{(S)}$ that never violates atomicity, is an interesting direction that we leave out for future work.

1.2 Other Related Work

Dynamic Reconfiguration: Our setting is closely related to the problem of implementing a consistent memory object in a dynamic setting, where nodes are allowed to voluntarily leave and join the
network. The problem involves dynamic reconfiguration of the set of nodes that take part in client operations, which is often implemented via a reconfig operation that is initiated by any of the participating processes, including the clients. Any node that wants to leave/join the network makes an announcement, via a leave/join operation, before doing so. The problem is extensively studied in the field of distributed algorithms [11], [12], [13], [14], [15]; review and tutorial articles appear in [16], [17], [18].

In our context, the problem of node repair could in fact be thought of as one of dynamic reconfiguration, wherein an involuntary crash is simulated by a voluntary leave operation without an explicit announcement. In this case, a new node joins as a replacement node via the join operation, which can be considered as the analogue of a repair operation. In the setting of dynamic reconfiguration, every node has a distinct identity; thus the replacement node joins the network with a new identity that is different from the identity of the crashed node [16]. This demands a reconfiguration of the set of participating nodes after every repair. Such reconfigurations get in the way of client operations, and add to the latency of read and write operations [18], in practical implementations. Clearly, a repair operation as considered in this work does not demand any reconfiguration, since a repaired node has the same identity as the crashed node. Also, the current work shows that modeling repair via a static system, permits design of algorithms where clients remain oblivious to the presence of repair operations. Furthermore, addressing storage and communication costs is not the focus of the works in dynamic reconfigurations; specifically, it is not known as to how erasure codes can be advantageously used in dynamic settings. Our RADONC algorithm shows that when repair is carried out under a static model, it is indeed possible to advantageously use erasure to reduce costs, when the number of concurrent writes are limited.

We make additional comparisons between our model and results to those found in works on dynamic reconfiguration. Several impossibility results exist in the context of implementing a dynamic atomic register and simultaneously guaranteeing liveness; the authors in [13] argue impossibility if there are infinitely many reconfigurations during an execution, while the authors in [14] argue an impossibility when there is no upper bound on message delay. We see, not surprisingly, that even in the problem of repair, we need to suitably limit the number of crash and repair operations that occur in an execution, even if all crash and repairs are sequentially ordered. In [15], the authors implement a dynamic atomic register under a model that has an (unknown) upper bound $D$ on any point-to-point message delay, and where the number of reconfigurations in any $D$ units of time is limited. Our network condition $N1$ is similar, except that 1) we limit the number of crash and repairs during any broadcast messaging, instead of point-to-point messaging, and 2) we do not assume any bound on the message delay. In practice, limiting number of repairs during broadcast instead of every point-to-point messaging offers resiliency against straggler nodes, which refer to the nodes having the worst delays among all nodes. We would also like to note that the algorithm in [15] does not guarantee atomicity, if the number of reconfigurations in $D$ units of time is higher than a set number. This appears similar to RADONR, where atomicity is not guaranteed if we do not satisfy stability condition $N1$. While we show how the slightly tighter model $N2$ can be used to always guarantee atomicity, it is an interesting question as to whether the model $N2$ can be adopted in the work of [15] so as to always guarantee atomicity.

**Repair-Efficient Erasure Codes for Distributed Storage:** Recently, a large class of new erasure/network codes for storage have been proposed (see [19] for a survey), and also tested in networks [20], [21], [22], where the focus is efficient storage of immutable data, such as, archival data. These new codes are specifically designed to optimize performance metrics like repair-bandwidth.
and repair-time (of failed servers), and offer significant performance gains when compared to the traditional Reed-Solomon MDS codes \cite{23}. It needs to be explored if these codes can be used in conjunction with the RADON$_C$ algorithm, to further improve the performance costs.

Other Works on using Erasure Codes: Applications of erasure codes to Byzantine fault tolerant DSSs are discussed in \cite{24}, \cite{25}, \cite{26}. In \cite{3}, the authors consider algorithms that use erasure codes for emulating regular registers. Regularity \cite{27}, \cite{28} is a weaker consistency notion than atomicity.

The rest of the document is organized as follows. Our system model appears in Section 2. The impossibility result, and the network stability conditions appear in Section 3. The three algorithms appear in Sections 4, 5 and 6, respectively. In Section 7, we discuss the storage and communication costs of the algorithms. Section 8 concludes the paper. Proofs of various claims appear in the Appendix.

2 Models and definitions

Processes and Asynchrony: We consider a distributed system consisting of asynchronous processes, each with a unique identifier (ID), of three types: a set of readers, $R$; a set of writers, $W$; and a set of $n$ servers, $S$. The readers and writers are together referred to as clients. The set $R \cup W \cup S$ forms a totally ordered set under some defined relation ($>$). The reader and writer processes initiate read and write operations respectively, and communicate with the servers using messages. A reader or writer can invoke a new operation only after all previous operations invoked by it has completed. The property is referred to as the well-formedness property of an execution. We assume that every client/server is connected to every other server via a reliable communication link; thus as long as the destination process is non-faulty, any message sent on the link eventually reaches the destination process.

Crash and Recovery: A client may fail at any point during the execution. At any point during the execution, a server can be in one (and only one) of the following three states: active, crashed or repair. A crash event triggers a server to enter the crashed state from an active state. The server remains in the crashed state for an arbitrary amount of time, but eventually is triggered by a repair event to enter the repair state. Crash and repair events are assumed to be externally triggered. A server in the repair state can experience another crash event, and go back to the crashed state. A server in the crashed state does not perform any local computation. The server also does not send or receive messages in the crashed state, i.e., any message reaching the server in a crashed state is lost. A server which enters the repair state has all its local state variables set to default values, i.e., a crash event causes the server to lose all its state variables. A server in the repair state can perform computations like in the active state.

Atomicity and Liveness: We aim to implement only one atomic read/write memory object, say $x$, under the MWMR setting on a set of servers, because any shared atomic memory can be emulated by composing individual atomic objects. The object value $v$ comes from some set $V$; initially $v$ is set to a distinguished value $v_0$ ($\in V$). Reader $r$ requests a read operation on object $x$. Similarly, a write operation is requested by a writer $w$. Each operation at a non-faulty client begins with an invocation step and terminates with a response step. An operation is incomplete when its invocation step does not have the associated response step; otherwise it is complete.

By liveness of a read or a write operation, we mean that during any well-formed execution, any read or write operation respectively initiated by a non-faulty reader or writer completes, despite
the crash failure of any other client. By liveness of repair associated with a crashed server, we mean that the server which enters a crashed state eventually re-enters the active state, unless it experiences a crash event during every repair operation that the server attempts. The liveness of repair holds despite the crash failure of any other client.

**Background on Erasure coding:** In RADONC, we use an \([n, k]\) linear MDS code over a finite field \(\mathbb{F}_q\) to encode and store the value \(v\) among the \(n\) servers. An \([n, k]\) MDS code has the property that any \(k\) out of the \(n\) coded elements can be used to recover (decode) the value \(v\). For encoding, \(v\) is divided into \(k\) elements \(v_1, v_2, \ldots v_k\) with each element having size \(\frac{1}{k}\) (assuming size of \(v\) is 1). The encoder takes the \(k\) elements as input and produces \(n\) coded elements \(c_1, c_2, \ldots, c_n\) as output, i.e., \([c_1, \ldots, c_n] = \Phi([v_1, \ldots, v_k])\), where \(\Phi\) denotes the encoder. For ease of notation, we simply write \(\Phi(v)\) to mean \([c_1, \ldots, c_n]\). The vector \([c_1, \ldots, c_n]\) is referred to as the codeword corresponding to the value \(v\). Each coded element \(c_i\) also has size \(\frac{1}{k}\). In our scheme we store one coded element per server. We use \(\Phi_i\) to denote the projection of \(\Phi\) on to the \(i^{th}\) output component, i.e., \(c_i = \Phi_i(v)\). Without loss of generality, we associate the coded element \(c_i\) with server \(i\), \(1 \leq i \leq n\).

**Storage and Communication Cost:** We define the total storage cost as the size of the data stored across all servers, at any point during the execution of the algorithm. The communication cost associated with a read or write operation is the size of the total data that gets transmitted in the messages sent as part of the operation. We assume that metadata, such as version number, process ID, etc. used by various operations is of negligible size, and is hence ignored in the calculation of storage and communication cost. Further, we normalize both the costs with respect to the size of the value \(v\); in other words, we compute the costs under the assumption that \(v\) has size 1 unit.

### 3 Network Stability Conditions

#### 3.1 An Impossibility Result

The crash and recovery model described in Section 2 does not impose any restriction on the rate of crash events, and repair operations that happen in the system. In other words, the model described above does not limit in any manner the number of crash events/repair operations, which can overlap with any a client operation. In [8], the authors showed that without such restrictions, it is impossible to implement a shared atomic memory service, which guarantees liveness of operations. Below, we state an impossibility result which holds even if there is at most one server in the crashed/repair state at any point during the execution. We then introduce network stability conditions that enable us impose restrictions on the number of crash/repair events that overlap with any operation.

**Theorem 1.** It is impossible to implement an atomic memory service that guarantees liveness of reads and writes, under the system model described in Section 2, even if 1) there is at most one server in the crashed/repair state at any point during the execution, and 2) every repair operation completes, and takes the repaired server back to the active state.

#### 3.2 Network Stability Conditions N1 and N2

We begin with the notions of a group-send operation, and effective consumption of a message.

---

\(1\) In practice \(v\) is a file, which is divided into many stripes based on the choice of the code, various stripes are individually encoded and stacked against each other. We omit details of representability of \(v\) by a sequence of symbols of \(\mathbb{F}_q\), and the mechanism of data striping, since these are fairly standard in the coding theory literature.
**group-send operation**: The group-send operation is used to abstract the operation of a process sending a list of \( n \) messages \( \{m_1, \ldots, m_n\} \) to the set of all \( n \) servers \( \{s_1, \ldots, s_n\} = S \), where message \( m_i \) is send to server \( s_i \), \( 1 \leq i \leq n \). Note that this is a mere abstraction of the process sending out \( n \) point-to-point messages sequentially to \( n \) servers, without interleaving the “send” operations with any significant local computations or waiting for any external inputs. The operation is no more powerful then sending \( n \) consecutive messages. The operation is written as \( \text{group-send}([m_1, m_2, \ldots, m_n]) \). In the event \( m_i = m, \forall i \), we simply write \( \text{group-send}(m) \). Our model allows the sender to fail while executing the group-send operation, in which case only a subset of the \( n \) servers receive their corresponding messages.

**Effective Consumption**: We say a process effectively consumes a message \( m \), if it receives \( m \), and executes all steps of the algorithm that depend only on the local state of the process, and the message \( m \); in other words, the process executes all the steps that do not require any further external messages.

**Definition 1 (Network Stability Conditions)**. Consider a process \( p \) executing a group-send \( ([m_1, m_2, \ldots , m_n]) \) operation, and consider the following statements:

(a) (i) There exists a subset \( S_\alpha \subseteq S \) of \( |S_\alpha| = \lceil \alpha n \rceil \) servers, \( 0 < \alpha < 1 \), all of which effectively consume their respective messages from the group-send operation, and (ii) all the servers in \( S_\alpha \) remain in the active state during the interval \( [T_1, T_2] \), where \( T_1 \) denotes the point of time of invocation of the group-send operation, and \( T_2 \) denotes the earliest point of time in the execution at which all of the servers in \( S_\alpha \) complete the effective consumption of their respective messages.

(b) Further, if effective consumption of the message \( m_i \) by server \( s_i \) involves sending a response back to the process \( p \), for all \( s_i \in S_\alpha \), then all servers in \( S_\alpha \) remain in the active state during the interval \( [T_1, T_3] \), where \( T_3 \) denotes the earliest point of time in the execution at which the process \( p \) completes effective consumption of the responses from the all the servers in \( S_\alpha \).

If the network satisfies Statement (a) for every execution of a group-send operation by any process, we say that it satisfies network stability condition \( N1 \) with parameter \( \alpha \). If the network satisfies Statements (a) and (b) for every execution of a group-send operation by any process, we say that it satisfies network stability condition \( N2 \) with parameter \( \alpha \).

Clearly, \( N2 \) implies \( N1 \). Note that the set \( S_\alpha \) which needs to satisfy the conditions need not be the same for various invocations of group-send operations by either the same or distinct processes. Also, note that in condition \( N2 \), the process \( p \) might crash before completing the effective consumption of the responses from the servers in \( S_\alpha \). In this case we only expect Statement (a) to be satisfied, and not Statement (b). Furthermore, in both \( N1 \) and \( N2 \), we do not expect any of these statements to be true, if process \( p \) crashes after partial execution of the group-send operation.

4 The \( \text{RADON}_R \) Algorithm

In this section, we present the \( \text{RADON}_R \) algorithm, and prove its liveness and atomicity properties for networks that satisfy the network condition \( N1 \) with \( \alpha > \frac{2}{3} \). We begin with some useful notation. Tags are used for version control of the object values. A tag \( t \) is defined as a pair \((z, w)\), where \( z \in \mathbb{N} \) and \( w \in \mathcal{W} \) denotes the ID of a writer. We use \( \mathcal{T} \) to denote the set of all the possible tags. For any two tags \( t_1, t_2 \in \mathcal{T} \), we say \( t_2 > t_1 \) if (i) \( t_2.z > t_1.z \) or (ii) \( t_2.z = t_1.z \) and \( t_2.w > t_1.w \). Note that \((\mathcal{T}, >)\) is a totally ordered set.
The protocols for writer, reader, and servers are shown in Fig. 1. Each server stores two state variables (i) \((t_{loc}, v_{loc})\) - a tag and value pair, initially set to \((t_0, v_0)\), (ii) \(status\) - a variable that can be in either active or repair state.

**Fig. 1** The protocols for writer, reader, and any server \(s \in S\) in \(RADON_R\).

write\((v)\):

- **get-tag**
  - group-send(query-tag)
  - Await responses from majority
  - Select the max tag \(t^*\)

- **put-data**
  - \(t_w = \lceil t^*z + 1, w \rceil\)
  - group-send((put-data, \((t_w, v)\)))
  - Terminate after \(\lceil \frac{3n+1}{4} \rceil\) acks.

read:

- **get-data**
  - group-send(query-tag-data)
  - Await responses from majority
  - Select \((t_r, v_r)\), with max tag.

- **put-data**
  - group-send((put-data, \((t_r, v_r)\)))
  - Wait for \(\lceil \frac{3n+1}{4} \rceil\) acks
  - Return \(v_r\)

Server \(s \in S\):

**State Variables**

\((t_{loc}, v_{loc}) \in T \times V\), initially \((t_0, v_0)\)

\(status \in \{\text{active}, \text{repair}\}\), initially active

get-tag-resp, recv query-tag from writer \(w\):

- if \(status = \text{active}\) then
  - Send \(t_{loc}\) to \(w\)

get-data-resp, recv query-tag-data from reader \(r\):

- if \(status = \text{active}\) then
  - Send \((t_{loc}, v_{loc})\) to \(r\)

put-data-resp, recv put-data, \((t, v)\) from client \(c\):

- if \(status = \text{active}\) then
  - if \(t > t_{loc}\) then
    - \((t_{loc}, v_{loc}) \leftarrow (t, v)\)
    - Send ack to \(c\).

init-repair:

- \(status \leftarrow \text{repair}\)
  - \((t_{loc}, v_{loc}) \leftarrow (t_0, v_0)\)
  - group-send(repair-tag-data)
  - Await responses from majority
  - Select \((t_{rep}, v_{rep})\), for max tag
  - \((t_{loc}, v_{loc}) \leftarrow (t_{rep}, v_{rep})\)
  - \(status \leftarrow \text{active}\)

init-repair-resp, recv repair-tag-data from \(s'\):

- if \(status = \text{active}\) then
  - Send \((t_{loc}, v_{loc})\) to \(s'\)

The write and read operations are very similar to those in the ABD algorithm [1], and each consists of two phases. In the first phase, get-tag, of a write operation \(\pi\), the writer queries all servers for local tags, awaits responses from a majority of servers, and selects the maximum tag \(t^*\) from among the responses. Next, the writer executes the put-data phase, during which a new tag \(t_w = tag(\pi)\) is created by incrementing the integer part of \(t^*\), and by incorporating the writer’s own ID. The writer then sends pair \((t_w, v)\) to all servers, and awaits acknowledgments (acks) from \(\lceil \frac{3n+1}{4} \rceil\) servers before completing the operation. The two phases are identical to those of the ABD algorithm [1], except for the fact that during the second phase, ABD expects acks from only a majority of servers, whereas here we need from \(\lceil \frac{3n+1}{4} \rceil\) servers. During a read operation \(\rho\), the reader in the get-data phase queries all the servers in \(S\) for the respective local tag and value pairs. Once it receives responses from a majority of servers in \(S\), it picks the pair with the highest tag, which we designate as \(t_r = tag(\pi)\). In the subsequent put-data phase, the reader writes back the tag \(t_r\) and the corresponding value \(v_r\) to all servers, and terminates after receiving acknowledgments from \(\lceil \frac{2n+1}{4} \rceil\) servers. Once again, we remark that both phases in the read are identical to those of the ABD algorithm, except for the difference in the number of the servers from which acks are
expected in the second write-back phase. Note that, during both the write and operations, a server responds to an incoming message only if it is in the active state.

A repair operation is initiated via the action \textit{init-repair}, by an external trigger, at a server which is in the crashed state. Note that we do not explicitly define a \textit{crashed} state since a crash is not a part of the algorithm. We assume that as soon as the repair operation starts, the variable \textit{status} is set to the \textit{repair} state, and also the local (tag, value) pair is set to the default state \((t_0, v_0)\). The repair operation is essentially the first phase of the read operation, during which the server queries all the servers for the respective local tag and value pairs, and stores the tag and value pair corresponding to the highest tag after receiving responses from a majority of servers. Finally, the repair operation is terminated setting variable \textit{status} to \textit{active} state. A server in \textit{S} responds to a request generated from \textit{init-repair} phase only if it is in the active state.

\subsection{Analysis of RADON\textsubscript{R}}

Liveness of read, write and repair operations in \textit{RADON\textsubscript{R}} follows immediately if we assume condition \textit{N1} with \(\alpha > \frac{3}{4}\). This is because liveness of any operation depends on sufficient number of responses from the servers during the various phases of the operation. From Fig. 1 we know that the maximum number of responses that is expected in any phase is \(\lceil \frac{3n+1}{4} \rceil\), which is guaranteed under \textit{N1} with \(\alpha > \frac{3}{4}\).

The tricky part is to prove atomicity of reads and writes. The proof is based on Lemma 13.16 of [31], a restatement of which can be found in [29]. Consider two completed write operations \(\pi_1\) and \(\pi_2\), such that, \(\pi_2\) starts after the completion of \(\pi_1\). For any completed write operation \(\pi\), we define \(tag(\pi) = t_w\), where \(t_w\) is the tag which the writer uses in the \textit{put-data} phase. In this case, one of the requirements the algorithm needs to satisfy to ensure atomicity is \(tag(\pi_2) > tag(\pi_1)\). While this fact is straightforward to prove for an algorithm like ABD, which does not have background repair, in \textit{RADON\textsubscript{R}}, we need to consider the effect of those repair operations that overlap with \(\pi_1\), and also those that occur in between \(\pi_1\) and \(\pi_2\). The point to note is that such repair operations can potentially restore the contents of the repaired node such that the restored tag is less than \(tag(\pi_1)\).

We then need to show the absence of propagation of older tags (older than \(tag(\pi_1)\)) into a majority of nodes, due to a sequence of repairs which happen before \(\pi_2\) decides its tag. We do this via the following two observations: 1) In Lemma 1, we show that any successful repair operation, which begins after a point of time \(T\), always restores value to one, which corresponds to a tag which is at least as high as the minimum of the tags stored in any majority of active servers at time \(T\). This fact is in turn used to prove a similar property for reads and writes, as well. 2) We next show (as part of proof of Theorem 4), under the assumption of \textit{N1} with \(\alpha > 3/4\), the existence of a point of time \(T\) before the completion of \(\pi_1\) such that a majority of nodes are active at \(T\), and all of whose tags are at least as high as \(tag(\pi_1)\). The two steps are together used to prove that \(tag(\pi_2) > tag(\pi_1)\). A similar sequence of steps are used to show atomicity properties of read operations, as well.

For a completed read operation \(\pi\), \(tag(\pi) = t_r\), where \(t_r\) is the tag corresponding to the value \(v_r\) returned by the reader. For a completed repair \(\pi\), \(tag(\pi) = t_{rep}\), where \(t_{rep}\) is the tag corresponding to the value restored during the repair operation.

\textbf{Lemma 1.} Let \(\beta\) denote a well-formed execution of \textit{RADON\textsubscript{R}}. Suppose \(T\) denotes a point of time in \(\beta\) such that there exists a majority of servers \(S_m\), \(S_m \subset S\) all of which are in the active state at time \(T\). Also, let \(t_s\) denote the value of the local tag at server \(s \in S_m\), at time \(T\). Then, if \(\pi\) denotes any completed repair or read operation that is initiated after time \(T\), we have \(tag(\pi) \geq \min_{s \in S_m} t_s\).
Also, if \( \pi \) denotes any completed write operation that is initiated after time \( T \), we have \( \text{tag}(\pi) > \min_{s \in S_n} t_s \).

**Theorem 2 (Liveness).** Let \( \gamma \) denote a well-formed execution of \( \text{RADON}_R \), under the condition \( N1 \) with \( \alpha > \frac{3}{4} \). Then every operation initiated by a non-faulty client completes.

**Theorem 3 (Atomcity).** Every execution of the \( \text{RADON}_R \) algorithm operating under the \( N1 \) network stability condition with \( \alpha > \frac{3}{4} \), is atomic.

We note that, though Lemma 1 gives a result about completed operations, condition \( N1 \) is not a prerequisite for the result in Lemma 1. In other words, the result in Lemma 1 holds for any completed operation, even if condition \( N1 \) is violated. As we will see, this is an important fact that we will use to establish atomicity of \( \text{RADON}^{(S)}_R \) for any execution.

### 5 Algorithm \( \text{RADON}_C \)

In this section, we present the erasure-code based \( \text{RADON}_C \) algorithm for implementing atomic memory service, and performing repair of crashed nodes. The algorithm uses \([n, k]\) MDS codes for storage. Liveness and atomicity are guaranteed under the following assumptions: 1) the \( N1 \) network stability condition with \( \alpha \geq \frac{3n+k}{4n} \), 2) the number of write operations concurrent with a read or repair operation is at most \( \delta \). The precise definition of concurrency depends on the algorithm itself, and appears later in this section. The \( \text{RADON}_C \) algorithm has significantly reduced storage and communication cost requirements than \( \text{RADON}_R \), when \( \delta \) is limited.

The algorithm (see Fig. 2) is a natural generalization of the \( \text{RADON}_R \) algorithm accounting for the fact that we use MDS codes. The write operation has two phases, where the first phase finds the maximum tag in the system based on majority responses. During the second phase, the writer computes the coded elements for each of the \( n \) servers and uses the group-send operation to disperse them. The group-send operation here uses a vector of length \( n \), where the \( i^{th} \) element denotes the message for the \( i^{th} \) server, \( 1 \leq i \leq n \). Each server keeps a List of up to \( (\delta + 1) \) (tag, coded-element) pairs. Every time a (tag, coded-element) message arrives from a writer, the pair gets added to the List, which is then pruned to at most \( (\delta + 1) \) pairs, corresponding to the highest tags. The writer terminates after getting acks from \( \left\lceil \frac{3n+k}{4n} \right\rceil \) servers.

During a read operation, the reader queries all servers for their entire local Lists, and awaits responses from \( \left\lceil \frac{n+k}{2} \right\rceil \) servers. Once the reader receives Lists from \( \left\lceil \frac{n+k}{2} \right\rceil \) servers, it selects the highest tag \( t_r \) whose corresponding value \( v_r \) can be decoded using the using the coded elements in the lists. The read operation completes following a write-back of \( (t_r, v_r) \) using the put-data phase.

The repair operation is very similar to the first phase of the read operation, during which a server collects lists from \( \left\lceil \frac{n+k}{2} \right\rceil \) servers. But this time, the server figures out the set of all the possible tags that can be decoded from among the Lists, and prunes the set to the highest \( (\delta + 1) \) tags. The repaired List then consists of (tag, coded-element) pairs corresponding these (at most) \( (\delta + 1) \) tags. Assuming repair of server \( i \), the creation of a coded-element corresponding to a value \( v \) involves first decoding the value \( v \), and then computing \( \Phi_i(v) \) (referred to as re-encoding in Fig. 2).

#### 5.1 Analysis of \( \text{RADON}_C \)

Throughout this section, we assume network stability condition \( N1 \) with \( \alpha \geq \frac{3n+k}{4n} \). Tags for completed read and write operations are defined in the same manner as we did for \( \text{RADON}_R \); we
avoid repeating them here. We first discuss liveness properties of $RADON_C$. Let us first consider liveness of repair operations. Towards this, note from the algorithm in Fig. 2 that a repair operation never gets stuck even if it does not find any set of $k$ Lists among the responses, all of which have a common tag. In such a case, the algorithm allows the possibility that the repaired List is simply empty, at the point of execution when the server re-enters the active state. In other words, liveness of a repair operation is trivially proved, i.e., a server in a repair state always eventually reenters the active state, as long as it does not experience a crash during the repair operation. The triviality of liveness of repair operations, observed above, does not extend to read operations. For a read operation to complete the get-data phase, it must be able to find a set of $k$ Lists among the responses all of which contain coded-elements corresponding to a common tag; otherwise a read operation gets stuck. The discussion above motivates the following definitions of valid read and valid repair operations.

**Definition 2 (Valid Read and Repair Operations).** A read operation will be called as a valid read if the associated reader remains alive at least until the reception of the $\lceil \frac{2n+k}{3} \rceil$ responses during the get-data phase. Similarly, a repair operation will be called a valid repair if the associated server does not experience a further crash event during the repair operation.
Definition 3 (Writes Concurrent with a Valid Read (Repair)). Consider a valid read (repair) operation $\pi$. Let $T_1$ denote the point of initiation of $\pi$. For a valid read, let $T_2$ denote the earliest point of time during the execution when the associated reader receives all the responses. For a valid repair, let $T_2$ denote the point of time during the execution when the repair completes, and takes the associated server back to the active state. Consider the set $\Sigma = \{\sigma : \sigma$ is any write operation that completes before $\pi$ is initiated$, and let $\sigma^* = \arg\max_{\sigma \in \Sigma} \{\text{tag}(\sigma)\}$. Next, consider the set $\Lambda = \{\lambda : \lambda$ is any write operation that starts before $T_2$ such that $\text{tag}(\lambda) > \text{tag}(\sigma^*)\}$. We define the number of writes concurrent with the valid read (repair) operation $\pi$ to be the cardinality of the set $\Lambda$.

The above definition captures all the write operations that overlap with the read, until the time the reader has all data needed to attempt decoding a value. However, we ignore those write operations that might have started in the past, and never completed yet, if their tags are less than that of any write that completed before the read started. This allows us to ignore write operations due to failed writers, while counting concurrency, as long as the failed writes are followed by a successful write that completed before the read started.

The following lemma could be considered as the analogue of Lemma 1 for RADON$_C$. The first part of the lemma shows that under Condition 1 with $\alpha \geq \frac{3n+k}{4n}$, the repaired List is never empty; there is always at least one (tag, coded-element) pair in the repaired List. Parts 2 and 3 are used to prove liveness and atomicity of client operations.

Lemma 2. Consider any well-formed execution $\beta$ of RADON$_C$ operating under the network stability condition $N1$ with $\alpha \geq \frac{3n+k}{4n}$. Further assume that the number of writes concurrent with any valid read or repair operation is at most $\delta$. For any operation $\pi$, consider the set $\Sigma = \{\sigma : \sigma$ is a read or a write in $\beta$ that completes before $\pi$ begins$, and also let $\sigma^* = \arg\max_{\sigma \in \Sigma} \text{tag}(\sigma)$. Then, the following statements hold:

- If $\pi$ denotes a completed repair operation on a server $s \in S$, then the repaired List of server $s$ due to $\pi$ contains the pair $(\text{tag}(\sigma^*), c^*_s)$.
- If $\pi$ denotes a read operation associated with a non-faulty reader $r$, and further, if $S_1$ denotes the set of $\left\lfloor \frac{n+k}{2} \right\rfloor$ servers whose responses, say $\{L_\pi(s), s \in S_1\}$, are used by $r$ to attempt decoding of a value in the get-data phase, then there exists $S_2 \subseteq S_1$, $|S_2| = k$, such that $\forall s \in S_2, (\text{tag}(\sigma^*), c^*_s) \in L_\pi(s)$.
- If $\pi$ denotes a write operation associated with a non-faulty writer $w$, and further if $S_1$ denotes the set of majority servers whose responses are used by $w$ to compute max-tag in the get-tag phase, then there exists a server $s \in S_1$, whose response tag $t_s \geq \text{tag}(\sigma^*)$.

Here, $c^*_s$ denotes the coded-element of server $s$ for value $v^*$, associated with $\text{tag}(\sigma^*)$.

Theorem 4 (Liveness). Let $\beta$ denote a well-formed execution of RADON$_C$, operating under the $N1$ network stability condition with $\alpha \geq \frac{3n+k}{4n}$ and $\delta$ be the maximum number of write operations concurrent with any valid read or repair operation. Then every operation initiated by a non-faulty client completes.

Theorem 5 (Atomicity). Any execution of RADON$_C$, operating under condition $N1$ with $\alpha \geq \frac{3n+k}{4n}$, is atomic, if the maximum number of write operations concurrent with a valid read or repair operation is $\delta$.  

Theorem 6 (Atomicity).
6  The $RADON^{(S)}_R$ Algorithm

In this section, we present the $RADON^{(S)}_R$ algorithm having the property that every execution is atomic. Liveness is guaranteed under the slightly stronger network stability condition $N\alpha^2$ with $\alpha > \frac{3}{4}$. In comparison with $RADON_R$, the algorithm has extra phases for both read and write operations, in order to guarantee safety of every execution.

**Fig. 3** The protocols for writer, reader, and any server $s \in S$ in $RADON^{(S)}_R$.

- **write($v$):**
  - **get-tag**
    - group-send (QUERY-TAG)
      - Await responses from majority
      - Select the max tag $t^*$
  - **put-data**
    - $t_w = (t^*, z + 1, w)$
    - group-send ([PUT-DATA], ($t_w, v$))
      - Wait for $\left\lceil \frac{n}{3n+1} \right\rceil$ acks (say from $S_0$)
    - **confirm-data**
      - Terminate after $\text{acks}$ from among servers in $S_0$

- **read:**
  - **get-data**
    - group-send (QUERY-TAG-DATA)
      - Await responses from majority
      - Select $(t_r, v_r)$, with max tag.
  - **put-data**
    - group-send ([PUT-DATA], ($t_r, v_r$))
      - Wait for $\left\lceil \frac{2n}{3n+1} \right\rceil$ acks (say from $S_0$)
    - **confirm-data**
      - Await $\text{acks}$ from a majority of servers in $S_0$
      - Return $v_r$

- **Server $s \in S$:**
  - **State Variables:**
    - $(t_{loc}, v_{loc}) \in T \times V$, initially $(t_0, v_0)$
    - $\text{status} \in \{\text{active}, \text{repair}\}$, initially active
    - $\text{Seen} \subseteq T \times (W \cup R)$, initially empty

- **get-tag-resp, recv QUERY-TAG from writer $w$:**
  - if $\text{status} = \text{active}$ then
    - Send $(t_{loc}, v_{loc})$ to $w$

- **get-data-resp, recv QUERY-TAG-DATA from reader $r$:**
  - if $\text{status} = \text{active}$ then
    - Send $(t_{loc}, v_{loc})$ to $r$

- **put-data-resp, recv (PUT-DATA, $(t, v)$) from $c$:**
  - if $\text{status} = \text{active}$ then
    - if $t > t_{loc}$ then
      - $(t_{loc}, v_{loc}) \leftarrow (t, v)$
      - $\text{Seen} \leftarrow \text{Seen} \cup \{(t, c)\}$
    - Send ack to $c$.

- **confirm-data-resp, recv (CONFIRM-DATA, $t$) from $c$:**
  - if $\text{status} = \text{active}$ then
    - if $(t, c) \in \text{Seen}$ then
      - Remove $(t, c)$ from $\text{Seen}$
      - Send ack to client $c$.

- **init-repair:**
  - status $\leftarrow \text{repair}$
  - $(t_{loc}, v_{loc}) \leftarrow (t_0, v_0)$
  - $\text{Seen} \leftarrow \emptyset$
  - group-send (REPAIR-TAG-DATA)
    - Await responses from majority.
    - Select $(t_{rep}, v_{rep})$, with max tag
      - $(t_{loc}, v_{loc}) \leftarrow (t_{rep}, v_{rep})$
      - status $\leftarrow \text{active}$

- **init-repair-resp, recv REPAIR-TAG-DATA from $s'$:**
  - if $\text{status} = \text{active}$ then
    - Send $(t_{loc}, v_{loc})$ to $s'$

The write operation has three phases (see Fig. 3). The first two phases are identical to those of $RADON_R$ during which the writer queries for the local tags, and then sends out the new (tag, value) pair, respectively. In the third phase, called confirm-data, the writer ensures the presence of at least a majority of servers, which the writer knows for sure that received its data during the second phase, put-data. In order to facilitate the confirm-data phase, the servers maintain a Seen variable. Any time the server receives a value from a writer, the server adds the corresponding (tag,
writer ID) pair to the Seen list. Next, during the confirm-data-resp phase, the server responds to the writer only if this (tag, writer ID) pair is part of the Seen variable. The idea is that if the server experiences a crash and a successful repair operation in between the put-data and confirm-data phases, the server no longer has the (tag, writer ID) pair in its Seen variable, and hence does not respond to the confirm-data phase. This is because, a crash removes all state variables, including Seen, and the repair algorithm (see Fig. 3) simply restores the Seen variable to its default value, the empty set. Further, by ensuring that the writer expects acks from among a majority of servers in confirm-data, from among the $\frac{3n+1}{4}$ servers whose acks were obtained during put-data, we can guarantee that any execution is atomic.

The read operation also has three phases, first two of which are identical to those of RADON$_R$, except for the use of the Seen variable in the server during the put-data phase. The third phase is the confirm-data phase as in the write operation. The repair operation has one phase, and is nearly exactly identical to that of RADON$_R$. Note that the Seen variable gets reset to its initial value during repair.

### 6.1 Analysis of RADON$_R^{(S)}$

We overview the proofs of liveness and atomicity before formal claims. For liveness of writes, we assume N2 with $\alpha > \frac{3}{4}$, and argue the existence of a majority $S_m$ of servers all of which remain active from the point of time at which the group-send operation gets initiated in the put-data phase, till the point of time all the servers in $S_m$ effectively consume requests for confirm-data from the writer. In this case, write operation completes after receiving acks from servers in $S_m$ during the confirm-data phase. The set $S_m$ exists because, under N2 with $\alpha > \frac{3}{4}$, a set $S_\alpha$ of $\left\lceil \frac{3n+1}{4} \right\rceil$ servers remain alive from the start of the group-send, till the effective consumption of the acks by the writer in put-data phase. Also, a second set $S'_\alpha$ of $\left\lceil \frac{3n+1}{4} \right\rceil$ servers remain active from the start of the group-send in the confirm-data phase, till all servers in $S'_\alpha$ complete the respective effective consumption from this group-send. We note that $S'_\alpha \cap S_\alpha$ is at least a majority. We next use the observation that the group-send operation in the confirm-data phase forms part of the effective consumption of the last of the acks in the put-data phase. Using this, we argue that the servers in $S'_\alpha \cap S_\alpha$ remain active till they effectively consume message from group-send operation of the confirm-data phase, and thus $S'_\alpha \cap S_\alpha$ is a candidate for $S_m$. The liveness of read is similar to that of write, while liveness of repair is straightforward under N2 with $\alpha > \frac{3}{4}$.

Towards proving atomicity of reads and writes, we first define tags for completed reads, writes and repair operations exactly in the same manner as we did in RADON$_R$. Consider two completed write operations $\pi_1$ and $\pi_2$ such that $\pi_2$ starts after the completion of $\pi_1$, and we need to show that $tag(\pi_2) > tag(\pi_1)$. As in RADON$_R$, we do this in two parts: Lemma 4 holds as it is for RADON$_R^{(S)}$ as well. Recall that Lemma 4 essentially shows that if a majority of active nodes is locked-on to any particular tag, say $t'$, at a specific point of time $T$ during the execution of the algorithm, then any repair operation which begins after the time $T$ always restores the tag to one which is at least as high as $t'$. The challenge now is to show the existence of these favorable points of time instants $T$ as needed in the assumption of the lemma. While in RADON$_R$, we used the N1 to argue this, in RADON$_R^{(S)}$, we do not use N2; instead we rely on the third confirm-data phase of the first write operation $\pi_1$.

**Theorem 6 (Liveness).** Let $\beta$ denote a well-formed execution of RADON$_R^{(S)}$ under condition N2 with $\alpha > \frac{3}{4}$. Then every operation initiated by a non-faulty client completes.
Theorem 7 (Atomcity). Every execution of the \( \text{RADON}_{(S)}^{(R)} \) algorithm is atomic.

7 Storage and Communication Costs of Algorithms

We give a justification of storage and communication cost numbers of the three algorithms, appearing in Table 1. Recall that the size of value \( v \) is assumed to be 1 and also that we ignore the costs due to metadata. It is clear that both \( \text{RADON}_{(S)}^{(R)} \) and \( \text{RADON}_{(S)}^{(R)} \) have storage cost \( n \), write cost \( n \), and read cost \( 2n \) (due to write back). For \( \text{RADON}_{(C)} \), each server stores at most \( \delta + 1 \) coded-elements, where each element has size \( \frac{1}{k} \). Thus storage cost of \( \text{RADON}_{(C)} \) is \( \frac{1}{k} n \). The write cost of \( \text{RADON}_{(C)} \) is simply \( n \), and the contribution comes from the writer sending one coded-element to each of the \( n \) servers. For a read, getting the entire \( \text{Lists} \) during the \( \text{get-data} \) phase incurs a cost of \( \frac{1}{k} (\delta + 1) \). The write-back phase incurs an additional cost of \( \frac{1}{k} n \). Thus, the total read cost in \( \text{RADON}_{(C)} \) is \( \frac{1}{k} (\delta + 2) \).

8 Conclusions

In this paper, we provided an erasure-code-based algorithm for implementing atomic memory, having the ability to perform repair of crashed nodes in the background, without affecting client operations. We assumed a static model with a fixed, finite set of nodes, and also a practical network condition \( N1 \) to facilitate repair. We showed how the usage of MDS codes significantly improve storage and communication costs over a replication based solution, when the number of writes concurrent with a read or repair is limited. Liveness and atomicity are guaranteed as long as \( N1 \) is satisfied; however violation of \( N1 \) can lead to non-atomic executions. We further showed how a slightly stringent network condition \( N2 \) can be used to construct a replication based algorithm that always guarantees atomicity. Ongoing efforts include exploring possibility of using repair-efficient erasure codes [19] in \( \text{RADON}_{(C)} \), and testbed evaluations on cloud based infrastructure.

Appendix

A Proof of Theorem \[1\]

The theorem is restated for convenience.

**Theorem 8. (Theorem \[1\])** It is impossible to implement an atomic memory service that guarantees liveness of reads and writes, under the system model described in Section \[2\], even if 1) there is at most one server in the crashed/repair state at any point during the execution, and 2) every repair operation completes, and takes the repaired server back to the active state.

**Proof.** We prove this result by contradiction, by assuming an algorithm \(A_{alg}\) that guarantees liveness and atomicity, and also is such that every repair operation completes, and takes the repaired server back to the active state. Let the initial value stored in the system be \(v_0 \in V\), where \(V\) is the domain of all values. Consider a non-faulty writer \(w\), and suppose \(w\) initiates a write operation \(\pi^w\) with the value \(v_1\), such that \(v_1 \neq v_0\). Let \(S_w \subseteq S\) be the set of all servers that writer \(w\) sends messages before \(w\) expects any response from any of the servers in \(S\). Without loss of generality, let \(S_w = \{s_1, s_2, \ldots, s_k\}\), for some \(k \leq n\), and let \(m_i\) denote the message sent by \(w\) to server \(s_i\), \(1 \leq i \leq k\). Note that if \(w\) sends two or messages to a particular server, say \(s_1\), all these can be combined into \(m_1\), since all these messages are sent without expecting any response.

Consider an execution which starts with all the servers in the active state, the operation \(\pi^w\) begins, messages get sent out to servers in \(S_w\). Delay the messages such that message \(m_1\) arrives at server \(s_1\) before any other server in \(S_w\) receives the respective message. Assume that \(s_1\) is in the crashed state when \(m_1\) arrives, so \(s_1\) does not receive \(m_1\). Further assume that all the other servers are in the active state at this point of execution. Let server \(s_1\) undergo a successful repair operation, before any other server in \(S_w\) receives its respective message. Next, consider the case when server \(s_2\) receives the message \(m_2\), and delay the messages to all other servers, and assume that \(s_2\) is in the crashed state when \(m_2\) arrives. The sequence of crash and repair can be carried out in this manner one-by-one for every server in \(S_w\), where all these servers end up losing the writer message, though they get repaired. Now if the algorithm is such that the writer expects a response from any of the servers in \(S\), clearly it will not happen, since no server in \(S\) has received any message from \(w\) while the server is in the active state. Thus liveness of write is compromised.

We next consider the case when the writer decides to terminate without expecting any response from any server in \(S\), and show that such a method of guaranteeing liveness results in violation of atomicity. Let us call this execution fragment (as discussed above) with such a write as \(\beta^w(v_1)\). After the write \(\pi^w\) completes, a read \(\pi^r\) associated with a non-faulty reader, begins. By liveness of read, and atomicity, the read must return \(v_1\). Let the execution fragment associated with the read be denoted as \(\beta^r\), so that the overall execution fragment under consideration is \(\beta^w(v_1) \circ \beta^r\). Next, consider the execution fragment \(\beta^w(v'_1)\) obtained by replacing \(v_1\) with \(v'_1\) such that \(v'_1 \neq v_1\). Since a crash causes a server to lose its entire state, it is clear that to the reader \(r\) there is no distinction between the state of the system after \(\beta^w(v_1)\), and the state of the system after \(\beta^w(v'_1)\). In this case, if we consider the execution \(\beta^w(v'_1) \circ \beta^r\), the read returns \(v_1\) (\(\neq v'_1\)), since in the execution \(\beta^w(v_1) \circ \beta^r\) also, \(r\) returned \(v_1\). However it violates atomicity of \(\beta^w(v'_1) \circ \beta^r\), which completes the proof.

\[2\] Clearly, the writer must send a message to at least one server, so we ignore the trivial case when \(S_w\) is empty.
B Proof of Lemma 1

The lemma is restated for convenience.

Lemma 3 (Lemma 1). Let $\beta$ denote a well-formed execution of the $\text{RADON}_R$ algorithm. Suppose $T$ denotes a point of time in the execution $\beta$ such that there exists a majority of servers $S_m$, $S_m \subset S$ all of which are in the active state at the time $T$. Also, let $t_s$ denote the value of the local tag at server $s$, at time $T$. Then, if $\pi$ denotes any completed repair or read operation that is initiated after time $T$, we have $\text{tag}(\pi) \geq \min_{s \in S_m} t_s$. Also, if $\pi$ denotes any completed write operation that is initiated after time $T$, then we have $\text{tag}(\pi) > \min_{s \in S_m} t_s$.

Proof. We use $\rho$ to denote $\min_{s \in S_m} t_s$. Also, for any state variable $x(s)$ that is stored in server $s$, we write $x(s)|_T$ to denote the value $x$ at time $T$. Below, we separately consider the cases when $\pi$ denotes a successful repair, read and write operations, in this respective order.

(a) $\pi$ is a successful repair operation: We prove the statement by contradiction, by starting with the assumption that $\text{tag}(\pi) < \rho$. Let $T_{\pi}$ denote the point of time in the execution $\beta$ at which the operation $\pi$ completes. Let $\Pi'_R$ denote the set of all successful repair operations which start after the time $T$, but start before $T_{\pi}$, and is such that $\forall \pi' \in \Pi'_R$, we have $\text{tag}(\pi') < \rho$. Clearly, $\pi \in \Pi'_R$. Let $\pi^* \in \Pi'_R$ denote the repair operation, which completes first. Note that $\pi^*$ exists since the set $\Pi'_R$ is finite. Now, let $\hat{S}$ denote the set of majority servers based on whose responses the operation $\pi^*$ completed. Clearly, $|\hat{S} \cap S_m| \geq 1$. For any server $s \in \hat{S} \cap S_m$, let $T_s$ denote the point of time in the execution at which the server $s$ responds to $\pi^*$ with its local $(\text{tag}, \text{value})$ pair. Clearly, the server $s$ must have remained in the active state during the entire interval $[T, T_s]$. This follows because $s$ is active at time $T$, $\pi^*$ is the first completed repair operation that started after $T$, and due to the fact that a server responds to a repair request only if it is in the active state. In this case, we know that $t_{\text{loc}}(s)|_{T_s} \geq t_{\text{loc}}(s)|_T \geq \rho$ for any $s$ in $\hat{S} \cap S_m$. Therefore, we have $\text{tag}(\pi^*) = \max_{s \in \hat{S}} t_{\text{loc}}(s)|_{T_s} \geq \max_{s \in \hat{S} \cap S_m} t_{\text{loc}}(s)|_{T_s} \geq \rho$, which contradicts the existence of $\pi^* \in \Pi'_R$. From, this we conclude that the set $\Pi'_R$ must be empty to avoid contradictions, and hence $\text{tag}(\pi) \geq \rho$.

(b) $\pi$ is a successful read operation: We prove this by contradiction by starting with the assumption that $\text{tag}(\pi) < \rho$. Let $\hat{S}$ denote the set of majority servers based on whose responses during the get-data phase (see Fig. 1), the read operation completed. As in Part a), we know that $|\hat{S} \cap S_m| \geq 1$. In this case, let $T_s$ denote the point of time during the execution at which the server $s \in \hat{S} \cap S_m$ responded to the reader. Next, note that in the get-data phase, the reader picks the response with the highest tag. Thus, since we assume that $\text{tag}(\pi) < \rho$, it must be true that $t_{\text{loc}}(s)|_{T_s} < \rho$, $s \in \hat{S} \cap S_m$. Since the server $s \in \hat{S} \cap S_m$ is active at time $T$ such that $t_{\text{loc}}(s)|_T \geq \rho$, this would imply that server $s$ experienced a crash event after time $T$, and came back to the active state before the time $T_s$ via a successful repair operation $\phi$ such that $\text{tag}(\phi) < \rho$. But then, this contradicts Part a) of the theorem which we proved above, and hence we conclude that $\text{tag}(\pi) \geq \rho$.

(c) $\pi$ is a write operation: Once again we prove via contradiction, by starting with the assumption that $\text{tag}(\pi) \leq \rho$. Let $\hat{S}$ denote the set of majority servers based on whose responses during the get-tag phase, the writer determined $\text{tag}(\pi)$. We know from the algorithm that $\text{tag}(\pi)$ is strictly larger than all the tags among the responses from $\hat{S}$. Since $|\hat{S} \cap S_m| \geq 1$, we argue like in Part b), and arrive at a contradiction to Part a).

---

3 Any read or write operation cannot decrease the local tag that is stored in an active server.
C Proof of Theorem 3

The theorem is restated here for convenience.

**Theorem 9 (Theorem 3).** Every execution of the RADON\textsubscript{R} algorithm operating under the N1 network stability condition with $\alpha > \frac{3}{4}$, is atomic.

C.1 Some Preliminaries

**Partial Order on read and write operations** Consider any well-formed execution $\beta$ of RADON\textsubscript{R}, all of whose invoked read or write operations complete. Let $\Pi_{\text{RW}}$ denote the set of all completed read and write operations in $\beta$. We first define a partial order ($\prec$) on $\Pi_{\text{RW}}$. Towards this, recall that for any completed write operation $\pi$, we defined $\text{tag}(\pi)$ as the tag created by the writer during the write-put phase. Also, recall that for any completed read operation $\pi$, we define $\text{tag}(\pi)$ as the tag corresponding to the value returned by the read. The partial order ($\prec$) in $\Pi_{\text{RW}}$ is defined as follows: For any $\pi, \phi \in \Pi_{\text{RW}}$, we say $\pi \prec \phi$ if one of the following holds: (i) $\text{tag}(\pi) < \text{tag}(\phi)$, or (ii) $\text{tag}(\pi) = \text{tag}(\phi)$, and $\pi$ and $\phi$ are write and read operations, respectively. The proof of atomicity is based on the following lemma, which is simply a restatement of the sufficiency condition for atomicity presented in [31].

**Lemma 4.** Consider any well-formed execution $\beta$ of the algorithm, such that all the invoked read and write operations complete. Now, suppose that all the invoked read and write operations in $\beta$ can be partially ordered by an ordering $\prec$, so that the following properties are satisfied:

P1. The partial order ($\prec$) is consistent with the external order of invocation and responses, i.e., there are no operations $\pi_1$ and $\pi_2$, such that $\pi_1$ completes before $\pi_2$ starts, yet $\pi_2 \prec \pi_1$.

P2. All operations are totally ordered with respect to the write operations, i.e., if $\pi_1$ is a write operation and $\pi_2$ is any other operation then either $\pi_1 \prec \pi_2$ or $\pi_2 \prec \pi_1$.

P3. Every read operation returns the value of the last write preceding it (with respect to $\prec$), and if no preceding write is ordered before it, then the read returns the initial value of the object.

Then, the execution $\beta$ is atomic.

C.2 Proof of Atomicity under N1 with $\alpha > 3/4$

We need to prove the properties P1, P2 and P3 of Lemma 4. We do this under N1 with $\alpha > 3/4$, using Lemma 1. Let $\phi$ and $\pi$ denote two operations in $\Pi_{\text{RW}}$ such that $\phi$ completed before $\pi$ started. Also, let $c_\phi$ and $c_\pi$ denote the clients that initiated the operations $\phi$ and $\pi$, respectively.

**Property P1** We want to show that $\pi \not\prec \phi$. We show this in detail only for the case when $\phi$ and $\pi$ are both write operations. The proofs of other three cases\footnote{These correspond to the case when $\phi$ and $\pi$ are both read operations, and the cases where one of them is a write and the other is a read.} are similar, and hence omitted. By virtue of the definition of the partial order $\prec$, it is enough to prove that $\text{tag}(\pi) > \text{tag}(\phi)$. Consider the put-data phase of $\phi$, where the writer sends the pair $(t_w, v)$ to all servers via the group-send operation. Under the condition N1 with $\alpha > 3/4$, we know that there exists a set $S_\alpha \subseteq S$ of $\lceil n\alpha \rceil \geq \lceil \frac{3n+1}{4} \rceil$ servers all of which remain in the active state during the interval $[T_1, T_2]$ where $T_1$
denotes the point of time of invocation of the group-send operation, and \( T_2 \) denotes the earliest point of time during the execution where all of the servers in \( S_\alpha \) complete their respective effective consumption (including sending ack to the writer \( c_\phi \)) of the message \((t_w, v)\). Also, let \( S' \subseteq S \) denote the set of \( \left\lceil \frac{3n+k}{4n} \right\rceil \) servers whose acks are used by the writer to decide the completion of the write operation. Clearly, \(|S' \cap S_\alpha| > \frac{n}{2}\). Let \( T \) denote the earliest point of time during the execution when all servers in \( S' \cap S_\alpha \) complete their respective effective consumption of the message \((t_w, v)\). In this case note that a) \( T \) occurs before the point of completion of the write operation, b) all servers in \( S' \cap S_\alpha \) are in the active state at \( T \), and c) \( t_{loc}(s)|_T \geq \text{tag}(\phi), \forall s \in S' \cap S_\alpha \). We now apply Lemma 1 to conclude that \( \text{tag}(\pi) > \text{tag}(\phi) \).

**Property P2** This follows from the construction of tags, and the definition of the partial order \((\prec)\).

**Property P3** This follows from the definition of partial order \((\prec)\), and by noting that value returned by a read operation \( \pi \) is simply the value associated with \( \text{tag}(\pi) \).

### D Proof of Lemma 2

The lemma is restated below for easy reference.

**Lemma 5 (Lemma 2).** Consider any well-formed execution \( \beta \) of RADON\(_C\) operating under the network stability condition N1 with \( \alpha \geq \frac{3n+k}{4n} \). Further assume that the number of writes concurrent with any valid read or repair operation is at most \( \delta \). For any operation \( \pi \), consider the set \( \Sigma = \{ \sigma : \sigma \text{ is a read or a write in } \beta \text{ that completes before } \pi \text{ begins} \} \), and also let \( \sigma^* = \arg \max_{\sigma \in \Sigma} \text{tag}(\sigma) \). Then, the following statements hold:

- If \( \pi \) denotes a completed repair operation on a server \( s \in S \), then the repaired List of server \( s \) due to \( \pi \) contains the pair \((\text{tag}(\sigma^*), e_s^*)\).
- If \( \pi \) denotes a read operation associated with a non-faulty reader \( r \), and further, if \( S_1 \) denotes the set of \( \left\lceil \frac{n+k}{2} \right\rceil \) servers whose responses, say \( \{L_\pi(s), s \in S_1\} \), are used by \( r \) to attempt decoding of a value in the get-data phase, then there exists \( S_2 \subseteq S_1 \), \(|S_2| = k\), such that \( \forall s \in S_2, (\text{tag}(\sigma^*), e_s^*) \in L_\pi(s) \).
- If \( \pi \) denotes a write operation associated with a non-faulty writer \( w \), and further if \( S_1 \) denotes the set of majority servers whose responses are used by \( w \) to compute max-tag in the get-tag phase, then there exists a server \( s \in S_1 \), whose response tag \( t_s \geq \text{tag}(\sigma^*) \).

Here, \( e_s^* \) denotes the coded-element of server \( s \) corresponding to the value \( v^* \), associated with \( \text{tag}(\sigma^*) \).

We prove the lemma separately for the cases of repair and read (Parts 1 and 2). The proof for the third part for the case of write operations to similar to that of Part 2, and hence omitted.

**Proof of Part 1 of Lemma 5** Consider the set \( \Sigma \) and the operation \( \sigma^* \) as defined in the statement of Lemma 5. Without loss of generality, let us assume that \( \sigma^* \) is a write operation. Since we assume condition N1 with \( \alpha \geq \frac{3n+k}{4n} \), there exists a set \( S_\alpha \) of \( \left\lceil \frac{3n+k}{n} \right\rceil \) servers that respects N1 for the group-send operation (say gp*) in the put-data phase of \( \sigma^* \). If \( S_1 \) denotes the set of \( \left\lceil \frac{3n+k}{n} \right\rceil \) servers, whose responses are used by the writer to decide termination, we then know that 1) \(|S_\alpha \cap S_1| \geq \frac{n+k}{2}\), and 2) if \( T_{prop} \) denotes the earliest point of time during the execution when all the servers in
$S_{\text{prop}} = S_a \cap S_1$ complete effective consumption of their respective messages from the group-send operation $\text{gp}^*$, then every server in $S_{\text{prop}}$ remains active at $T_{\text{prop}}$, and has not experienced a crash after its effective consumption, until $T_{\text{prop}}$. Our goal is to show that the repair operation $\pi$ always receives at least $k$ responses from among the servers in $S_{\text{prop}}$, and must be able to decode (and then re-encode) the value corresponding to $\text{tag}(\sigma^*)$. Below we consider the effects of concurrent writes having higher tags, and repairs before $\pi$ starts, both of which can potentially remove coded elements corresponding to $\text{tag}(\sigma^*)$, from lists of various servers. We show under the assumptions of the lemma, that neither of these cause a problem.

Let us first consider the effect of concurrent writes. Towards this, consider the set $A$ of writes concurrent with the valid repair operation $\pi$ (see Definition 3). Recall that $A = \{ \lambda : \lambda$ is a write operation that starts before $\pi$, such that $\text{tag}(\lambda) > \text{tag}(\sigma^*) \}$. By assumption on the lemma, we know that $|A| \leq \delta$. In this case, it is clear that if a server $s \in S_{\text{prop}}$ does not crash in the interval $[T_{\text{prop}} T]$, the $\text{List}(s)|_T$ contains the pair corresponding to $\text{tag}(\sigma^*)$, for any $T$ such that $T_{\text{prop}} \leq T \leq T_{\text{end}}(\pi)$. Here $T_{\text{end}}(\pi)$ denotes the point of completion of $\pi$.

Let us next consider the effect of repairs, let $\bar{\pi} = \{ \tilde{\pi} : \text{a repair which start after } T_{\text{prop}}, \text{but also start before the completion of } \pi \}$. Clearly, $\pi \in \bar{\pi}$. Let $\pi^* \in \bar{\pi}$ denote the repair operation that completes first. Clearly, it must be true that $T_{\text{prop}} < T_{\text{end}}(\pi^*) \leq T_{\text{end}}(\pi)$. We prove Part 1 of the Lemma 5 for $\pi^*$ first. Using this result, we prove the lemma for the repair operation in $\bar{\pi}$ which completes second. We continue in an inductive manner (on the finite set $\bar{\pi}$), until we hit $\pi$. Towards proving the lemma for $\pi^*$, consider the group-send operation, where $\pi^*$ requests for local Lists from all servers. Let $S_\theta \subset S_{\text{prop}}$ denote the servers among $S_{\text{prop}}$ which are not in the active state when the repair request arrives. Also, let $S_a \subset S$ denote the set of all servers which are in the active state when the repair request arrives. Clearly, $|S_a| \leq n - |S_\theta|$. Next, let $S_{\text{ack}} \subset S_a$ denote the set of $\left\lceil \frac{n+k}{2} \right\rceil$ servers based on whose responses the repair operation $\pi^*$ completes. Now, since $S_{\text{prop}} \setminus S_\theta \subset S_a$, we have

\begin{align}
(S_{\text{prop}} \setminus S_\theta) \cup S_{\text{ack}} & \subset S_a \tag{1} \\
|S_{\text{prop}} \setminus S_\theta| + |S_{\text{ack}}| - |(S_{\text{prop}} \setminus S_\theta) \cap S_{\text{ack}}| & \leq S_a \tag{2} \\
|S_{\text{prop}}| - |S_\theta| + \left\lceil \frac{n+k}{2} \right\rceil - |(S_{\text{prop}} \setminus S_\theta) \cap S_{\text{ack}}| & \leq n - |S_\theta| \tag{3} \\
\Rightarrow |(S_{\text{prop}} \setminus S_\theta) \cap S_{\text{ack}}| & \geq k, \tag{4}
\end{align}

where the last inequality follows from our earlier observation that $|S_{\text{prop}}| \geq \left\lceil \frac{n+k}{2} \right\rceil$. Next, note that any server $s$ in $(S_{\text{prop}} \setminus S_\theta) \cap S_{\text{ack}}$ remains active from $T_{\text{prop}}$ until the point when $s$ responds to the repair request from $\pi^*$. This follows because of the facts that 1) $s$ is active at $T_{\text{prop}}$, 2) a server responds to a repair request only if it is in the active state, and 3) since $\pi^*$ is the first repair operation that completes after $T_{\text{prop}}$. Also, recall our earlier observations that 1) if a server $s \in S_{\text{prop}}$ does not crash in the interval $[T_{\text{prop}} T]$, then $\text{List}(s)|_T$ contains the pair corresponding to $\text{tag}(\sigma^*)$, for any $T$ such that $T_{\text{prop}} \leq T \leq T_{\text{end}}(\pi)$, and 2) $T_{\text{prop}} < T_{\text{start}}(\pi^*) < T_{\text{end}}(\pi^*) \leq T_{\text{end}}(\pi)$. In this case, we know that the responses of all the servers in $(S_{\text{prop}} \setminus S_\theta) \cap S_{\text{ack}}$ to $\pi^*$, contain the pair corresponding to $\text{tag}(\sigma^*)$. From (4), it follows that the repaired list for $\pi^*$, before pruning to $(\delta + 1)$ entries, contains the pair corresponding to $\text{tag}(\sigma^*)$. Finally the fact that $\text{tag}(\sigma^*)$ is among the highest $\delta + 1$ tags, and hence part of the pruned list, follows from our earlier observations that $\delta$.

\footnote{Note that $\Lambda$ need not be the set of writes concurrent with $\pi^*$. The above argument where we say that the pruned list, after the repair $\pi^*$, is of size at most $\delta + 1$ can be argued entirely based on $\Lambda$ itself.}
1) $|A| \leq \delta$, and 2) $T_{end}(\pi^*) \leq T_{end}(\pi)$. This completes our proof of Part 1 of Lemma 5 for the repair operation $\pi^*$.

We next prove the lemma for the repair operation $\pi_2 \in \tilde{I}$, which completes second. The proof is mostly identical, and we will only highlight the place where we use the result on $\pi^*$. Clearly, since we carry out the induction only until we hit $\pi$, it must be true that $T_{prop} < T_{end}(\pi_2) \leq T_{end}(\pi)$.

Consider the group-send operation, where $\pi_2$ requests for local Lists from all servers. Let $\mathcal{S}_{\theta}^{(2)} \subseteq \mathcal{S}_{prop}$ denote the servers among $\mathcal{S}_{prop}$ which are not in the active state when the repair request arrives. Also, let $\mathcal{S}_a^{(2)} \subseteq \mathcal{S}$ denote the set of all servers which are in the active state when the repair request arrives. As before, $|\mathcal{S}_a^{(2)}| \leq n - |\mathcal{S}_{\theta}^{(2)}|$. Next, let $\mathcal{S}_{ack}^{(2)} \subseteq \mathcal{S}_a^{(2)}$ denote the set of $\lceil \frac{n-k}{2} \rceil$ servers based on whose responses the repair operation $\pi_2$ completes. Along the lines of (1) - (4), one can show that $|\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)} \cap \mathcal{S}_{ack}^{(2)}| \geq k$. Next, if we consider the set $(\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)}) \cap \mathcal{S}_{ack}^{(2)}$, at most one of the servers in this set would have undergone a crash after the time $T_{prop}$, and got repaired before the time the server responded to $\pi_2$. Note that more than one repair operation on $(\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)}) \cap \mathcal{S}_{ack}^{(2)}$ cannot happen, since this will contradict the assumption that $\pi_2$ is the second repair operation to complete after $T_{prop}$. Further, if one repair operation among a server in $(\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)}) \cap \mathcal{S}_{ack}^{(2)}$ has indeed occurred, this must be the operation $\pi^*$ which we considered above. Further, we know that the repaired List due to $\pi^*$ contains the pair corresponding to $\text{tag}(\sigma^*)$. In other words, irrespective of whether one repair operation occurred among the servers in $(\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)}) \cap \mathcal{S}_{ack}^{(2)}$ or not, the responses of all the servers in $(\mathcal{S}_{prop} \setminus \mathcal{S}_{\theta}^{(2)}) \cap \mathcal{S}_{ack}^{(2)}$ contain the pair corresponding to $\text{tag}(\sigma^*)$. The rest of the proof is similar to that of $\pi^*$, where we argue that the pruned list after repair contains the pair corresponding to $\text{tag}(\sigma^*)$. The rest of the induction is similar, and this completes the proof of Part 1 of Lemma 5.

**Proof of Part 2 of Lemma 5** The proof follows mostly along the lines of proof of Part 1 of the lemma. We will only highlight the main steps here. Consider the set $\Sigma$ and the operation $\sigma^*$ as defined in the statement of the lemma. Without loss of generality, let us assume that $\sigma^*$ is a write operation. Also, define the time $T_{prop}$ and the set $\mathcal{S}_{prop}$ exactly in the same way as what we defined in the proof of Part 1 of the lemma. Let $T_1$ denote the earliest point of time during the execution when the reader receives responses from all the servers in $\mathcal{S}_1$, where $\mathcal{S}_1$ is as defined in the statement of this lemma. Consider the set of writes concurrent with the valid read operation $\pi$. Recall from Definition 3 that $A = \{ \lambda : \lambda$ is a write operation which starts before time $T_1$ such that $\text{tag}(\lambda) > \text{tag}(\sigma^*) \}$. From the assumption on concurrency in the lemma statement, we know that $|A| \leq \delta$. In this case, it is clear (like in the proof of Part 1 above) that if a server $s \in \mathcal{S}_{prop}$ does not crash in the interval $[T_{prop}, T_1]$, the List($s$)$_{\mid T}$ contains the pair corresponding to $\text{tag}(\sigma^*)$, for any $T$ such that $T_{prop} \leq T \leq T_1$. Now, if server $s \in \mathcal{S}_{prop}$ undergoes a crash and repair operation (say $\rho$) during the interval $[T_{prop}, T]$ (so that it is active again at $T$), we can argue exactly like in the proof of Part 1 above, and show that the repaired List due to $\rho$ contains the pair corresponding to $\text{tag}(\sigma^*)$. This can be done by considering the set $\tilde{I} = \{ \pi : \text{a repair which start after } T_{prop}, \text{but also start before } T_1 \}$, and applying induction on $\tilde{I}$ based on the order of completion times of the repair operations. The completes the proof of our claim about List($s$)$_{\mid T}$.

The rest of the proof follows simply by noting $|\mathcal{S}_1 \cap \mathcal{S}_{prop}| \geq k$, and thus the value corresponding to $\text{tag}(\sigma^*)$ is surely a candidate for decoding, since we know that an $[n,k]$ linear MDS code can be uniquely decoded given any $k$ out of the $n$ coded-elements.

22
E  Liveness: Proof of Theorem 4

The theorem is restated below for easy reference:

**Theorem 10.** (Theorem 4) Let $\beta$ denote a well-formed execution of $\text{RADON}_C$, operating under the $N1$ network stability condition with $\alpha \geq \frac{3n+k}{4n}$ and $\delta$ be the maximum number of write operations concurrent with any valid read or repair operation. Then every operation initiated by a non-faulty client completes.

*Proof.* Liveness of writes depends only on sufficient number of responses in the two phases. The maximum number of responses expected in either of the two phases is $\frac{3n+k}{4n}$, which we know is guaranteed under $N1$ with $\alpha \geq \frac{3n+k}{4n}$. Liveness of reads follows by combining Lemma 2 (for decodability of a value), and the liveness of write operations (for the write-back phase).

F  Atomicity: Proof of Theorem 5

The theorem is restated first:

**Theorem 11.** (Theorem 5) Any execution of $\text{RADON}_C$, operating under condition $N1$ with $\alpha \geq \frac{3n+k}{4n}$, is atomic, if the maximum number of write operations concurrent with a valid read or repair operation is $\delta$.

*Proof.* The proof is based on Lemmas 4 and 2. In order to apply Lemma 4 consider any well-formed execution $\beta$ of $\text{RADON}_C$, all of whose invoked read and write operations, denoted by the set $\Pi_{RW}$, complete. We define a partial order ($\prec$) on $\Pi_{RW}$ like in the proof of Theorem for case of $\text{RADON}_R$. To prove Property $P1$ of Lemma 4 consider two successful operations $\phi$ and $\pi$ such that $\phi$ completes before $\pi$ begins. Firstly, consider the case $\pi$ is a write, and $\phi$ is either a read or write. We need to show that $\text{tag}(\pi) > \text{tag}(\phi)$, which we note follows directly from Part 3 of Lemma 2. Next, consider the case when $\pi$ is a read, and $\phi$ is either a read or write. We need to show that $\text{tag}(\pi) \geq \text{tag}(\phi)$, which we note follows directly from Part 2 of Lemma 2. This completes the proof of Property $P1$. Proofs of Properties $P2$ and $P3$ are similar to those of the corresponding properties in Theorem 3, where we proved atomicity of $\text{RADON}_R$.

G  Proof of Theorem 6

The theorem is restated for convenience.

**Theorem 12.** (Theorem 6) Let $\beta$ denote a well-formed execution of $\text{RADON}_R^{(S)}$ operating under condition $N2$ with $\alpha > \frac{3}{4}$. Then every operation initiated by a non-faulty client completes.

We will prove that a write operation associated with a non-faulty client always completes, the proof for a read is similar and hence is omitted. The main step is to show the completion of the confirm-data phase. Consider the put-data phase, and note that under $N2$ with $\alpha > \frac{3}{4}$, we are guaranteed that there exists of set of $\mathcal{S}_\alpha \subset \mathcal{S}$ servers, such that 1) $|\mathcal{S}_\alpha| \geq \left\lceil \frac{3n+1}{4} \right\rceil$, and 2) every server in $\mathcal{S}_\alpha$ remains active from the point of time $T_1$ of initiation of the group-send operation of put-data phase till the point of time $T'_1$, when the writer effectively consumes all responses (acks) from the servers in $\mathcal{S}_\alpha$. Next, let $\mathcal{S}_1 \subset \mathcal{S}$ denote the set of $\left\lceil \frac{3n+1}{4} \right\rceil$ whose acks are received by the
writer before moving on to the confirm-data phase. First of all note that the existence of the set \( S_1 \) is clearly guaranteed under N2 with \( \alpha > \frac{3}{4} \) (since the set \( S_\alpha \) is a candidate for \( S_1 \)). Secondly, we note that the group-send operation in the confirm-data phase forms part of the effective consumption of the last ack that is received from the servers in \( S_1 \). This follows from the definition of effective-consumption, and by noting the execution of the group-send operation in the confirm-data phase does not depend on any more input after all the acks in the put-data phase are received. Let \( T_2 \) denote the point of time at which the group-send operation in the confirm-data phase gets initiated. Note that \( T_1' \geq T_2 \), in fact if \( S_1 \neq S_\alpha \), we have \( T_1' > T_2 \). Next we apply the network condition to the group-send operation in the confirm-data phase. From the N1 part of N2, we know that there exists a \( S_\alpha' \) of \( \lceil \frac{3n+1}{4} \rceil \) servers, all of which receive and effectively consume the message from the group-send operation, and remain active from \( T_2 \) till the point of time \( T_2' \) when the last of the servers in \( S_\alpha' \) completes effective consumption. Now if we let \( S_\gamma = S_\alpha \cap S_\alpha' \), observe that 1) \( |S_\gamma| > \frac{n}{2} \), and 2) all the servers in \( S_\gamma \) remain active from \( T_1 \) till \( T_2' \). The second part follows from our earlier observation that \( T_1' \geq T_2 \). In this case, we infer that all the servers in \( S_\gamma \) does indeed acknowledge back to writer as part of their effective consumption of the confirm-data message, and since \( S_\gamma \subseteq S_\alpha \) is at least a majority, we conclude that the write operation associated with the non-faulty writer eventually completes.

### H Proof of Theorem 7

**Theorem 13.** *(Theorem 7)* Every execution of the \( \text{RADON}^{(S)}_R \) algorithm is atomic.

#### H.1 Some Preliminaries

The proof is based on Lemma 4 and the equivalent of Lemma 4 for \( \text{RADON}^{(S)}_R \), which we state below for the sake of completion:

**Lemma 6.** Let \( \beta \) denote a well-formed execution of \( \text{RADON}^{(S)}_R \). Suppose \( T \) denotes a point of time in \( \beta \) such that there exists a majority of servers \( S_m, S_m \subseteq S \) all of which are in the active state at time \( T \). Also, let \( t_s \) denote the value of the local tag at server \( s \) at time \( T \). Then, if \( \pi \) denotes any completed repair or read operation that is initiated after time \( T \), we have \( \text{tag}(\pi) \geq \min_{s \in S_m} t_s \). Also, if \( \pi \) denotes any completed write operation that is initiated after time \( T \), we have \( \text{tag}(\pi) > \min_{s \in S_m} t_s \).

**Proof.** Similar to the proof of Lemma 4

Next, in order to apply Lemma 4 consider any well-formed execution \( \beta \) of \( \text{RADON}^{(S)}_R \), all of whose invoked read and write operations, denoted by the set \( \Pi_{\text{RW}} \), complete. Recall the discussion in Section 6 where we noted that tags for completed operations in \( \text{RADON}^{(S)}_R \) are defined exactly

\[ \text{tag}(\pi) = \max_{s \in S_m} t_s \]

In this case, some of the acks from the servers in \( S_\alpha \) get effectively consumed only after the required number \( \lceil \frac{3n+1}{4} \rceil \) have already been consumed, the last of which includes execution of the group-send operation of the confirm-data phase. We note that the effective consumption of these additional acks from servers in \( S_\alpha \) is the operation where server simply ignores these, which is not explicitly mentioned in the algorithm. We also note that the notion of atomicity of any sequences of effective consumptions that are local to a server, is implicitly used when we argue that \( T_1' > T_2 \). By this we mean that if a server receives a message \( m_1 \) before \( m_2 \), the effective consumption of message \( m_1 \) is assumed to be entirely completed before the effective consumption of the message \( m_2 \) starts.
as we had done for RADON$_R$. Thus, for any completed write operation $\pi$, we define $\text{tag}(\pi)$ as the tag created by the writer during the write-put phase. For any completed read operation $\pi$, we define $\text{tag}(\pi)$ as the tag corresponding to the value returned by the read. Further, we define a partial order ($\prec$) on $\Pi_{RW}$ like in the proof of Theorem 3 for case of RADON$_R$. These are restated for the sake of completion: For any $\pi, \phi \in \Pi_{RW}$, we say $\pi \prec \phi$ if one of the following holds: (i) $\text{tag}(\pi) < \text{tag}(\phi)$, or (ii) $\text{tag}(\pi) = \text{tag}(\phi)$, and $\pi$ and $\phi$ are write and read operations, respectively.

### H.2 Proof of Atomicity

**Property P1** Consider two successful operations $\phi$ and $\pi$ such that $\phi$ completes before $\pi$ begins. We want to prove that $\pi \not\prec \phi$. Consider the case when both $\phi$ and $\pi$ are write operations (the other cases are similar, so only one case is discussed). By virtue of the definition of the partial order ($\prec$), it is enough to prove that $\text{tag}(\pi) > \text{tag}(\phi)$. Let $S_\alpha$ and $S_1$ respectively denote the set of servers whose responses were used by the writer during the put-data and confirm-data phases of $\phi$. Let $T$ denote the time of initiation of the confirm-data phase of $\phi$. From the algorithm (see Fig. 3), we know that $S_1 \subset S_\alpha$. Further, based on the algorithm, it is clear that all servers in $S_1$ (which is a majority) are active at time $T$, such that $t_{loc}(s)|_T \geq \text{tag}(\phi)$. In this case, we apply Lemma 6 to conclude that $\text{tag}(\pi) > \text{tag}(\phi)$.

**Property P2** This follows from the construction of tags, and the definition of the partial order ($\prec$).

**Property P3** This follows from the definition of partial order ($\prec$), and by noting that value returned by a read operation $\pi$ is simply the value associated with $\text{tag}(\pi)$.
