Abstract: We give a clear yet rigorous correctness proof for Moss’s algorithm for managing data in a nested transaction system. The algorithm, which is the basis of concurrency control and recovery in the Argus system, uses read- and write-locks and a stack of versions of each object to ensure the serializability and recoverability of transactions accessing the data. Our proof extends earlier work on exclusive locking to prove that Moss’s algorithm generates serially correct executions in the presence of concurrency and transaction aborts. The key contribution is the identification of a simple property of read operations, called transparency, that permits shared locks to be used for read operations.

Keywords: nested transactions, atomic actions, concurrency control, recovery, databases, serializability, readlocks, writelocks.

1. Introduction

A major part of database research over several years has been the design and analysis of algorithms to maintain consistent data in the face of interleaved accesses, aborts of operations, replication of information and failures of system components. The most popular and simple protocol is two phase locking with separate read and write locks; other methods include arbitrary conflict-based locking, timestamp-based techniques, and locking that uses special structure of the data (e.g. a hierarchical arrangement) \([Gr,T,KS,Ko,We]\). A powerful theory has been developed to prove the correctness of these algorithms, based on the idea that a protocol is correct if it ensures that all executions are equivalent to serial executions \([EGLT,P,BG]\). This theory proves serializability by showing that a precedence graph contains no cycles.

Recently, some ideas in database system design and more general distributed system design have led several research groups to study the possibility of giving more structure to the transactions that are the basic unit of atomicity. When a transaction can contain concurrent operations that are to be performed atomically, or operations which can be aborted independently, we say that the operations form subtransactions of the original transaction. Thus we consider a system where transactions can be nested. This idea was first suggested by Davies under the name spheres of control \([D]\). A primitive example of this concept is implemented in System R, where a recovery block can be aborted and the transaction restarted at the last savepoint. In general distributed systems like Argus \([LiS,LHJLSW]\) or Clouds \([A]\), the basic services are often provided by Remote Procedure Calls which, at their best ("At Most Once" semantics), are atomic. Since providing a service will often require using other services, the transactions that implement services ought to be nested.

The implementation of a nested transaction system requires extending the algorithms that have previously been considered for concurrency control, recovery and replication. The work of Reed \([R]\) extended multi-version timestamp concurrency control to provide nested transaction data management. Moss \([Mo]\) extended two phase locking with separate read and write locks to handle nesting, and this algorithm is the basis of data management in the Argus system implemented at MIT.

This paper is part of a major research effort to offer clean, readable descriptions of algorithms for managing data in a nested transaction system, together with rigorous proofs of the correctness of these algorithms. Other parts of the project include studying replicated data management algorithms, orphan elimination algorithms and general atomicity of abstract objects. All this work is based on a simple model of concurrent systems using I/O automata and an operational style of reasoning about their schedules. The first fruits of this program are detailed in \([LM]\), which proves the correctness of exclusive locking, and provides a basic framework for presenting the ideas of this paper.
This paper's contribution is threefold. First, it proves for the first time the correctness of Moss' algorithm, an algorithm which has been used in practice. Our discussion covers both concurrency control and recovery from aborts. However, we do not consider all the failure cases that the real system must deal with, as our model does not yet include crashes that compromise the system state. Second, we provide technical definitions (for *equi-effectiveness* and *transparency*) that seem to capture exactly those properties of read operations depended on by the algorithm. Third, this paper provides another example of the power and value of the basic model of serial correctness first proposed in [LM], and of the operational style of reasoning with I/O automata.

In this paper we first review the I/O automaton model of computation. This is very similar to models like Communicating Sequential Processes [Ho], in that automata interact by synchronizing on shared operations. The main difference from other models is that we distinguish the input and output operations of each automaton. Any operation shared between components of a system can be an output of at most one component, and that component is in control of the operation, because no automaton is allowed to refuse to execute an input. Though automata have states as well as operations, we concentrate our analysis on the sequence of operations performed (the *schedule* of the system) - this operational mode of reasoning is quite different from assertion-based invariant methods used elsewhere in reasoning about distributed systems, but we find it very powerful and yet simple for the set of problems we consider.

Next, we show how to use I/O automata to model the parts of a nested transaction system. Each transaction is represented by an automaton, as is each data object. The actions of calling a subtransaction, invoking an access to an object, and returning a result are each split into two operations, one requesting the action and one delivering the request to the recipient. The request operation is an output of the caller and an input to the scheduler (which acts as a communication system) while the delivery operation is an output of the scheduler and an input of the recipient. Thus, each transaction (and each object) shares operations only with the scheduler. A *serial system* is the result of composing transaction and object automata with a *serial scheduler*, which runs the subtransactions of any transaction sequentially (with no concurrency between siblings) and only aborts transactions before they start running. The serial scheduler is very simple to understand and is used as the basis of our correctness condition.

We then introduce a *R/W Locking system* to model a system using Moss' locking algorithm to manage data. We use a new sort of I/O automaton called a *R/W Locking object*, which is like the object automaton of the serial system, but which maintains lock tables and versions of the object so that it can respond correctly when aborts occur. It also delays operations until it is permitted to respond by the locking rules. We also use a new sort of scheduler called a *generic scheduler*, which transmits requests to the appropriate recipient with arbitrary delay, allowing siblings to run concurrently or to abort after
performing some work. A R/W Locking system is the result of composing the transaction automata, R/W Locking objects and generic scheduler.

A R/W Locking system allows more concurrency than a serial system, but it is correct in the sense (first suggested in [LM]) that each transaction that does not have an aborted ancestor is unable to tell whether it is running in a R/W Locking system or in a serial system. The proof of this correctness condition is the main result of this paper.

The proof proceeds by taking an arbitrary schedule of a R/W Locking system (a concurrent schedule) and explicitly showing how to rearrange the operations to get a schedule of the serial system. The permitted rearrangements (which do not alter the sequence of events at any transaction) are those that are write-equivalent to the original sequence.

A key contribution of this paper is in identifying exactly the properties of read and write accesses that are required to guarantee correctness of Moss' algorithm. Write accesses require no special properties. However, it is necessary that read accesses leave the object in "essentially" the same state as they found it. We define equieffective schedules to be those that leave the object in "essentially" the same state, where "essentially" means "as far as later operations can detect". Then an object schedule with a read access appended is required to be equieffective to the same schedule without the read access.

There have been several other attempts to provide rigorous proofs of the correctness of algorithms for data management in nested transaction systems. The first was [Ly], which presented a model that successfully handled exclusive locking, but which proved difficult to extend to more complicated problems such as orphan elimination [Go]. The main deficiencies of this earlier model seem to be the lack of distinction between inputs and outputs, and the lack of explicit representations for transactions and their interfaces. These deficiencies were remedied in [LM], where the operational model discussed above was defined; this paper again proved correctness of exclusive locking. This paper continues the work of [LM] by dealing with an algorithm with separate read and write locks. (The result of this paper implies a main result of [LM], since when no accesses are distinguished as read accesses, Moss' algorithm degenerates into exclusive locking.) A different program to study concurrency control in nested transaction systems has been offered in [BBGLS,BBG], where a major motivation is to analyze protocols that operate on data at different levels of abstraction, but where recovery is not considered. The argument for the correctness of Moss' algorithm in [BBG] considers only the locking rules and not the state maintenance methods, so correctness is proved only in the absence of aborts. Concurrency control and recovery algorithms are also analyzed in [MGG], but [MGG] is also concerned mainly with levels of abstraction.

This paper uses many concepts from [LM], but we have repeated everything needed to make it self-contained, and indicated where definitions or details differ. In Section 2, we review the model of I/O
automata of [LT,LM]. In Section 3, we define the automata that make up the serial system, namely the transaction automata, the basic object automata and the serial scheduler. In Section 4, we specify the semantic conditions that read accesses must satisfy, using the technical notion of equieffective schedules. In Section 5 we define the automata of the R/W Locking system, namely the R/W Locking objects (which have code based directly on the algorithm of [Mo]) and the generic scheduler, and prove the main lemmas that relate the schedules of R/W Locking objects to the schedules of the basic objects. Finally in Section 6 we prove that R/W Locking systems are serially correct at transactions no ancestor of which has aborted, and in particular at the root transaction which represents the external environment.

2. I/O Automata

The following is a brief introduction to a model which is described in [LM] and developed at length, with extensions to express infinite behavior, in [LT].

All components in our systems, transactions, objects and schedulers, will be modelled by I/O automata. An I/O automaton $A$ has a set of states, some of which are designated as initial states. It has operations, each classified as either an input operation or an output operation. Finally, it has a transition relation, which is a set of triples of the form $(s', \pi, s)$, where $s'$ and $s$ are states, and $\pi$ is an operation. This triple means that in state $s'$, the automaton can atomically do operation $\pi$ and change to state $s$. An element of the transition relation is called a step of the automaton. The output operations are intended to model the actions that are triggered by the automaton itself, while the input operations model the actions that are triggered by the environment of the automaton.

Given a state $s'$ and an operation $\pi$, we say that $\pi$ is enabled in $s'$ if there is a state $s$ for which $(s', \pi, s)$ is a step. We require the following condition.

**Input Condition:** Each input operation $\pi$ is enabled in each state $s'$.

This condition says that an I/O automaton must be prepared to receive any input operation at any time.

An execution of $A$ is a finite alternating sequence $s_0, \pi_1, s_1, \pi_2, \ldots, s_n, \pi_n$ of states and operations of $A$, beginning and ending with a state. Furthermore, $s_0$ is a start state of $A$, and each triple $(s', \pi, s)$ which occurs as a consecutive subsequence is a step of $A$. From any execution, we can extract the schedule, which is the subsequence of the execution consisting of operations only. Because transitions to different states may have the same operation, different executions may have the same schedule. We say that a schedule $\alpha$ of $A$ can leave $A$ in state $s$ if there is some execution of $A$ with schedule $\alpha$ and final state $s$. We say that an operation $\pi$ is enabled after a schedule $\alpha$ of $A$ if there exists a state $s$ such that $\alpha$ can leave $A$ in state $s$ and $\pi$ is enabled in $s$. Since the same operation may occur several times in an execution or schedule, we refer to a single occurrence of an operation as an event.
We describe systems as consisting of interacting components, each of which is an I/O automaton. It is convenient and natural to view systems as I/O automata, also. Thus, we define a composition operation for I/O automata, to yield a new I/O automaton. A set of I/O automata may be composed to create a system \( S \), if the sets of output operations of the various automata are pairwise disjoint. (Thus, every output operation in \( S \) will be triggered by exactly one component.) A state of the composed automaton is a tuple of states, one for each component, and the start states are tuples consisting of start states of the components. The operations of the composed automaton are those of the component automata. Thus, each operation of the composed automaton is an operation of a subset of the set of component automata. An operation is an output of the composed automaton exactly if it is an output of some component. (The output operations of a system are intended to be exactly those that are triggered by components of the system, while the input operations of a system are those that are triggered by the system's environment.)

During an operation \( \pi \) of a composed automaton, each of the components which has operation \( \pi \) carries out the operation, while the remainder stay in the same state.

An execution or schedule of a system is defined to be an execution or schedule of the automaton composed of the individual automata of the system. If \( \alpha \) is a schedule of a system with component \( A \), then we denote by \( \alpha | A \) the subsequence of \( \alpha \) containing all the operations of \( A \). Clearly, \( \alpha | A \) is a schedule of \( A \).

The following lemma from [LM] expresses formally the idea that an operation is under the control of the component of which it is an output.

**Lemma 1:** Let \( \alpha' \) be a schedule of a system \( S \), and let \( \alpha = \alpha' \pi \), where \( \pi \) is an output operation of component \( A \). If \( \alpha | A \) is a schedule of \( A \), then \( \alpha \) is a schedule of \( S \).

**Proof:** Since \( \alpha | A \) is a schedule of \( A \), there is an execution \( \beta \) of \( A \) with schedule \( \alpha | A \). Let \( \beta' \) be the execution of \( A \) consisting of all but the last step of \( \beta \). Similarly, since \( \alpha' \) is a schedule of \( S \), there is an execution \( \gamma \) of \( S \) with schedule \( \alpha' \). It is possible that \( A \) has an execution in \( \gamma \) which is different from \( \beta' \), since different executions may have the same schedule. But it is easy to show, by induction on the length of \( \gamma \), that there is another execution \( \gamma' \) of \( S \) in which component \( A \) has execution \( \beta' \), and which is otherwise identical to \( \gamma \). The schedule of \( \gamma' \) is \( \alpha' \). Since \( \pi \) is not an output operation of any other component, \( \pi \) is defined from the state reached at the end of \( \gamma' \), so that \( \alpha = \alpha' \pi \) is a schedule of \( S \). \( \square \)

We say that automaton \( A \) preserves a property \( P \) of schedules of \( A \) if \( \alpha = \alpha' \pi \) satisfies \( P \) whenever \( \alpha \) is a schedule \( A \), \( \alpha' \) satisfies \( P \) and \( \pi \) is an output of \( A \).

### 3. Serial Systems

In this paper we define two kinds of systems: "serial systems" and "R/W Locking systems". Serial systems describe serial execution of transactions. They are defined for the purpose of giving a correctness condition for other systems, namely that the schedules of another system should look like schedules of the serial system to the transactions. As with serial executions of single-level transaction systems, serial
systems are too inefficient to use in practice. Thus, we will define R/W Locking systems, which allow transactions to run concurrently or abort after performing some work; these systems use Moss' algorithm to maintain locks and enough information to restore the states of objects after aborts occur.

In this section of the paper we define serial systems, which consist of transactions and basic objects communicating with a serial scheduler. Transactions and basic objects describe user programs and data, respectively. The serial scheduler controls communication between the other components, and thereby controls the orders in which the transactions create children or access data. All the system components are modelled as I/O automata. Most of this section is taken from [LM], with slight modifications to accomodate slight changes in definitions.

We represent the pattern of transaction nesting by a system type, which is a set of transaction names. The transaction names are organized into a tree by the mapping "parent()", with T₀ as the root. In referring to this tree, we use traditional terminology, such as child, leaf, least common ancestor (lca), ancestor and descendant. (A transaction is its own ancestor and descendant.) The leaves of this tree are called accesses. The accesses are partitioned, where each element of the partition contains the accesses to a particular object. The partition, including the names of the objects, is part of the system type. The tree structure can be thought of as a predefined naming scheme for all possible transactions that might ever be invoked. In any particular execution, however, only some of these transactions will actually take steps. We imagine that the tree structure is known in advance by all components of a system. The tree will, in general, be an infinite structure with infinite branching.

The classical transactions of concurrency control theory (without nesting) appear in our model as the children of a "mythical" transaction, T₀, the root of the transaction tree. (In work on nested transactions, such as Argus, the children of T₀ are often called "top-level" transactions.) It is very convenient to introduce the new root transaction to model the environment in which the rest of the transaction system runs. Transaction T₀ has operations that describe the invocation and return of the classical transactions. It is natural to reason about T₀ in the same way as about all of the other transactions. The only transactions which actually access data are the leaves of the transaction tree, and thus they are distinguished as "accesses". The internal nodes of the tree model transactions whose function is to create and manage subtransactions, but not to access data directly.

We also assume that a system type includes a designated set V of values, to be used as return values of transactions.

A serial system of a given system type is the composition of a set of I/O automata. This set contains a transaction automaton for each internal (i.e. non-leaf, non-access) node of the transaction tree, a basic object automaton for each object, and a serial scheduler. These automata are described below.
3.1. Transactions

This paper differs from other work such as [BBG] in that we model the transactions explicitly. A non-access transaction \( T \) is modelled as an I/O automaton, with the following operations.

Input operations:

\[
\text{CREATE}(T)
\]

\[
\text{REPORT\_COMMIT}(T', v), \text{ for } T' \text{ a child of } T, \text{ and } v \text{ a value}
\]

\[
\text{REPORT\_ABORT}(T'), \text{ for } T' \text{ a child of } T
\]

Output operations:

\[
\text{REQUEST\_CREATE}(T'), \text{ for } T' \text{ a child of } T
\]

\[
\text{REQUEST\_COMMIT}(T, v), \text{ for } v \text{ a value}
\]

The CREATE input operation "wakes up" the transaction. The REQUEST\_CREATE output operation is a request by \( T \) to create a particular child transaction. The REPORT\_COMMIT input operation reports to \( T \) the successful completion of one of its children, and returns a value recording the results of that child's execution. The REPORT\_ABORT input operation reports to \( T \) the unsuccessful completion of one of its children, without returning any other information. We call REPORT\_COMMIT\( (T', v) \), for any \( v \), and REPORT\_ABORT\( (T') \) report operations for transaction \( T' \). The REQUEST\_COMMIT operation is an announcement by \( T \) that it has finished its work, and includes a value recording the results of that work.

It is convenient to use two separate operations, REQUEST\_CREATE and CREATE, to describe what takes place when a subtransaction is activated. The REQUEST\_CREATE is an operation of the transaction's parent, while the actual CREATE takes place at the subtransaction itself. In actual systems such as Argus, this separation does occur, and the distinction will be important in our results and proofs. Similarly, we distinguish between a subtransaction's REQUEST\_COMMIT, the actual COMMIT (which is internal to the scheduler, see Section 3.3), and the REPORT\_COMMIT operation of the parent transaction. We leave the executions of particular transaction automata largely unspecified; the choice of which children to create, and what value to return, will depend on the particular implementation. For the purposes of the schedulers studied here, the transactions (and in large part, the objects) are "black boxes." Nevertheless, it is convenient to assume that schedules of transaction automata obey certain syntactic constraints. We therefore require that all transaction automata preserve well-formedness, as

\[
\text{Note that there is no provision for } T \text{ to pass information to its child in this request. In a programming language, } T \text{ might be permitted to pass parameter values to a subtransaction. Although this may be a convenient descriptive aid, it is not necessary to include it in the underlying formal model. Instead, we consider transactions that have different input parameters to be different transactions.}
\]

\[
\text{Note that we do not include a REQUEST\_ABORT operation for a transaction: we do not model the situation in which a transaction decides that its own existence is a mistake. Rather, we assign decisions to abort transactions to another component of the system, the scheduler. In practice, the scheduler must have some power to decide to abort transactions, as when it detects deadlocks or failures. In Argus, transactions are permitted to request to abort; we regard this request simply as a "hint" to the scheduler, to restrict its allowable executions in a particular way.}
\]
defined in the next paragraph. We do not constrain the operation of a transaction automaton after schedules that violate well-formedness, but we will prove later that, when placed in any of the systems we consider, a transaction generates only well-formed schedules.

We recursively define well-formedness for sequences of operations of transaction T. Namely, the empty schedule is well-formed. Also, if \( \alpha = \alpha' \pi \) is a sequence of operations of T, where \( \pi \) is a single event, then \( \alpha \) is well-formed provided that \( \alpha' \) is well-formed, and the following hold.

- If \( \pi \) is CREATE(T), then
  (i) there is no CREATE(T) event in \( \alpha' \).

- If \( \pi \) is REPORT\_COMMIT(T',v) for a child T' of T, then
  (i) REQUEST\_CREATE(T') appears in \( \alpha' \) and
  (ii) there is no REPORT\_ABORT(T') event in \( \alpha' \) and
  (iii) there is no REPORT\_COMMIT(T',v') event with \( v' \neq v \) in \( \alpha' \).

- If \( \pi \) is REPORT\_ABORT(T') for a child T' of T, then
  (i) REQUEST\_CREATE(T') appears in \( \alpha' \) and
  (ii) there is no REPORT\_COMMIT event for T' in \( \alpha' \).

- If \( \pi \) is REQUEST\_CREATE(T') for a child T' of T, then
  (i) there is no REQUEST\_CREATE(T') event in \( \alpha' \) and
  (ii) there is no REQUEST\_COMMIT event for T in \( \alpha' \) and
  (iii) CREATE(T) appears in \( \alpha' \).

- If \( \pi \) is REQUEST\_COMMIT(T,v) for a value v, then
  (i) there is no REQUEST\_COMMIT event for T in \( \alpha' \) and
  (ii) CREATE(T) appears in \( \alpha' \).

These restrictions are very basic; they simply say that a transaction does not get created more than once, does not receive conflicting information about the fates of its children, and does not receive information about the fate of any child whose creation it has not requested; also, a transaction does not perform any output operations before it has been created or after it has requested to commit, and does not request the creation of the same child more than once. Except for these minimal conditions, there are no a priori restrictions on allowable transaction behavior.

The following easy lemma summarizes the properties of well-formed sequences of transaction operations.

**Lemma 2:** Let \( \alpha \) be a well-formed sequence of operations of transaction T. Then the following conditions hold.

1. The first event in \( \alpha \) is a CREATE(T) event, and there are no other CREATE events.
2. If a REQUEST\_COMMIT event for T occurs in \( \alpha \), then there are no later output events of T in \( \alpha \).
3. There is at most one REQUEST\_CREATE(T') event for each child T' of T, in \( \alpha \).
4. There are not two different report operations in \( \alpha \) for any child T' of T. (However, there may be several events which are repeated instances of a single report operation).
5. Any report event for a child T' of T is preceded by REQUEST\_CREATE(T') in \( \alpha \).

Conversely, any sequence of operations of T satisfying these conditions is well-formed.
3.2. Basic Objects

Recall that I/O automata are associated with non-access transactions only. Since access transactions model abstract operations on shared data objects, we associate a single I/O automaton with each object, rather than one for each access. The operations for each object are just the CREATE and REQUEST_COMMIT operations for all the corresponding access transactions. Although we give these operations the same names as the operations of non-access transactions, it is helpful to think of the operations of access transactions in other terms also: a CREATE corresponds to an invocation of an operation on the object, while a REQUEST_COMMIT corresponds to a response by the object to an invocation. Actually, these CREATE and REQUEST_COMMIT operations generalize the usual invocations and responses in that our operations carry with them a designation of the position of the access in the transaction tree. Thus, a basic object X is modelled as an automaton, with the following operations.

Input operations:
CREATE(T), for T an access to X

Output operations:
REQUEST_COMMIT(T,v), for T an access to X

As with transactions, while specific objects are left largely unspecified, it is convenient to require that schedules of basic objects satisfy certain syntactic conditions. We recursively define well-formedness for sequences of operations of basic objects. Namely, the empty schedule is well-formed. Also, if \( \alpha = \alpha'\pi \) is a sequence of operations of basic object X, where \( \pi \) is a single event, then \( \alpha \) is well-formed provided that \( \alpha' \) is well-formed, and the following hold.

- If \( \pi \) is CREATE(T), then
  (i) there is no CREATE(T) event in \( \alpha' \).

- If \( \pi \) is REQUEST_COMMIT(T,v) for a value v, then
  (i) there is no REQUEST_COMMIT event for T in \( \alpha' \), and
  (ii) CREATE(T) appears in \( \alpha' \).

These restrictions simply say that the same access does not get created more than once, and that a basic object does not respond more than once to any access, and only responds to accesses that have previously been created. These requirements constrain the environment of the object slightly less than those in [LM]; the added freedom makes some of the arguments slightly simpler. We require that every basic object preserve well-formedness (this is a simple syntactic condition). The following easy lemma summarizes the properties of well-formed sequences of basic object operations.

**Lemma 3:** Let \( \alpha \) be a well-formed sequence of operations of basic object X. Then for any access T to X, \( \alpha \) contains one of the following
(i) no CREATE(T) and no REQUEST_COMMIT(T,v) events, or
(ii) one CREATE(T) and no REQUEST_COMMIT(T,v) events, or
(iii) one CREATE(T) event and following that one REQUEST_COMMIT(T,v) event for some v.
Conversely, any $\alpha$ satisfying this condition is well-formed.

If $\alpha$ is a well-formed sequence of operations of $X$ and $T$ is an access to $X$ such that $\alpha$ contains \texttt{CREATE(T)} but no \texttt{REQUEST\_COMMIT(T,v)}), we say that $T$ is pending in $\alpha$.

The following lemmas explore the conditions under which we can deduce that an extension of a well-formed sequence is itself well-formed.

\textbf{Lemma 4:} Suppose $\alpha$, $\beta$, and $\gamma$ are all well-formed sequences of operations of basic object $X$ such that the events in $\beta$ are a subset of the events in $\alpha$ (though not necessarily in the same order) and the events in $\gamma$ are a subset of the events in $\beta$. Let $\phi$ be a sequence of operations of $X$ such that both $\alpha\phi$ and $\gamma\phi$ are well-formed. Then $\beta\phi$ is well-formed.

\textbf{Proof:} Since $\beta$ is well-formed we need only check for each event $\pi$ in $\phi$ the presence and absence of certain operations preceding $\pi$ in $\beta\phi$. Any operation whose presence is needed is present in $\gamma\phi$ since $\gamma\phi$ is well-formed, and hence is present in $\beta\phi$, while similarly any operation whose absence is required is absent in $\alpha\phi$ and thus in $\beta\phi$. \hfill $\square$

\textbf{Lemma 5:} Suppose $\alpha$ and $\beta$ are well-formed sequences of operations of basic object $X$ which contain the same events (perhaps in different orders). Let $\phi$ be a sequence of operations of $X$. Then if $\alpha\phi$ is well-formed so is $\beta\phi$.

\textbf{Lemma 6:} Suppose $\alpha$, $\beta$, and $\gamma$ are sequences of operations of basic object $X$ such that $\alpha\beta$ is well-formed, and the set of accesses whose operations occur in $\gamma$ is disjoint from the set of accesses whose operations occur in $\beta$. Then $\alpha\beta\gamma$ is well-formed if and only if $\alpha\gamma$ is well-formed.

3.3. Serial Scheduler

The third kind of component in a serial system is the serial scheduler. The serial scheduler is also modelled as an automaton. Whereas the transactions and basic objects have been specified to be any I/O automata whose operations and behavior satisfy simple syntactic restrictions, the serial scheduler is a fully specified automaton, particular to each system type. It runs transactions according to a depth-first traversal of the transaction tree. The serial scheduler can choose nondeterministically to abort any transaction after its parent has requested its creation, as long as the transaction has not actually been created. In the context of this scheduler, the "semantics" of an \texttt{ABORT(T)} operation are that transaction $T$ was never created. Each child of $T$ whose creation was requested must be either aborted or run to commitment with no siblings overlapping its execution, before $T$ can commit. The operations of the serial scheduler are as follows.

\begin{itemize}
  \item Input Operations:
    \begin{itemize}
      \item \texttt{REQUEST\_CREATE(T)}
      \item \texttt{REQUEST\_COMMIT(T,v)}
    \end{itemize}
  \item Output Operations:
    \begin{itemize}
      \item \texttt{CREATE(T)}
      \item \texttt{COMMIT(T), T \neq T_0}
      \item \texttt{ABORT(T), T \neq T_0}
      \item \texttt{REPORT\_COMMIT(T,v), T \neq T_0}
      \item \texttt{REPORT\_ABORT(T), T \neq T_0}
    \end{itemize}
\end{itemize}
The REQUEST_CREATE and REQUEST_COMMIT inputs are intended to be identified with the corresponding outputs of transaction and object automata, and correspondingly for the CREATE, REPORT_COMMIT and REPORT_ABORT output operations. The COMMIT and ABORT operations are internal, marking the point in time where the decision on the fate of the transaction is irrevocable. We call COMMIT(T) and ABORT(T) return operations for T.

Each state s of the serial scheduler consists of six sets, named with record notation: s.create_requested, s.created, s.commit_requested, s.committed, s.aborted and s.returned. The set s.commit_requested is a set of (transaction,value) pairs. The others are sets of transactions. There is exactly one initial state, in which the set create_requested is \( \{T_0\} \), and the other sets are empty.

The transition relation consists of exactly those triples \((s',\pi,s)\) satisfying the pre- and postconditions below, where \(\pi\) is the indicated operation. For brevity, we include in the postconditions only those conditions on the state \(s\) which may change with the operation. If a component of \(s\) is not mentioned in the postcondition, it is implicit that the set is the same in \(s'\) and \(s\).

REQUEST_CREATE(T)
Postcondition:
\[ s.\text{create\_requested} = s'.\text{create\_requested} \cup \{T\} \]

REQUEST_COMMIT(T,v)
Postcondition:
\[ s.\text{commit\_requested} = s'.\text{commit\_requested} \cup \{(T,v)\} \]

CREATE(T)
Precondition:
\[ T \in s'.\text{create\_requested} - (s'.\text{created} \cup s'.\text{aborted}) \]
\[ \text{siblings}(T) \cap s'.\text{created} \subseteq s'.\text{returned} \]
Postcondition:
\[ s.\text{created} = s'.\text{created} \cup \{T\} \]

COMMIT(T), \( T \neq T_0 \)
Precondition:
\[ (T,v) \in s'.\text{commit\_requested} \text{ for some } v \]
\[ T \notin s'.\text{returned} \]
\[ \text{children}(T) \cap s'.\text{create\_requested} \subseteq s'.\text{returned} \]
Postcondition:
\[ s.\text{committed} = s'.\text{committed} \cup \{T\} \]
\[ s.\text{returned} = s'.\text{returned} \cup \{T\} \]

ABORT(T), \( T \neq T_0 \)
Precondition:
\[ T \in s'.\text{create\_requested} - (s'.\text{created} \cup s'.\text{aborted}) \]
\[ \text{siblings}(T) \cap s'.\text{created} \subseteq s'.\text{returned} \]
Postcondition:
\[ s.\text{aborted} = s'.\text{aborted} \cup \{T\} \]
\[ s.\text{returned} = s'.\text{returned} \cup \{T\} \]
REPORT_ABORT(T), T \neq T_0

Precondition:
T \in s'.aborted

REPORT_COMMIT(T, v), T \neq T_0

Precondition:
T \in s'.committed
(T, v) \in s'.commit_requested

The input operations, REQUEST_CREATE and REQUEST_COMMIT, simply result in the request being recorded. A CREATE operation can only occur if a corresponding REQUEST_CREATE has occurred and the CREATE has not already occurred. The second precondition on the CREATE operation says that the serial scheduler does not create a transaction until all its previously created sibling transactions have returned. That is, siblings are run sequentially. The precondition on the COMMIT operation says that the scheduler does not allow a transaction to commit until its children have returned. The precondition on the ABORT operation says that the scheduler does not abort a transaction while any of its siblings are active. That is, aborted transactions are dealt with sequentially with respect to their siblings. The result of a transaction can be reported to its parent at any time after the (purely internal) commit or abort has occurred. In particular, siblings might run in one order and be reported to their parent in the opposite order.

One significant difference between our serial scheduler and the one in [LM] is that there the return operation and the report to the parent of the return are combined as a single operation, giving the parent the extra information of the order in which its children are run.

The next lemma relates a schedule of the serial scheduler to the state which results from applying that schedule.

Lemma 7: Let \alpha be a schedule of the serial scheduler, and let s be a state which can result from applying \alpha to the initial state. Then the following conditions are true.
1. T is in s.create_requested exactly if T = T_0 or \alpha contains a REQUEST_CREATE(T) event.
2. T is in s.created exactly if \alpha contains a CREATE(T) event.
3. (T, v) is in s.commit_requested exactly if \alpha contains a REQUEST_COMMIT(T, v) event.
4. T is in s.committed exactly if \alpha contains a COMMIT(T) event.
5. T is in s.aborted exactly if \alpha contains an ABORT(T) event.
6. s.returned = s.committed \cup s.aborted.
7. s.committed \cap s.aborted = \emptyset.
3.4. Serial Systems and Serial Schedules

The composition of transactions with basic objects and the serial scheduler for a given system type is called a serial system, and its operations and schedules are called serial operations and serial schedules, respectively. We note that every serial operation is an operation of the serial scheduler, and of at most one other component of the serial system. A sequence $\alpha$ of serial operations is said to be well-formed provided that its projection at every transaction and basic object is well-formed.

**Lemma 8:** Let $\alpha$ be a serial schedule. Then $\alpha$ is well-formed.

**Proof:** By induction on the length of schedules. The base, length $= 0$, is trivial. Suppose that $\alpha \pi$ is a serial schedule, and assume that $\alpha$ is well-formed. If $\pi$ is an output of a basic object or non-access transaction $P$, then $\alpha \pi |P$ is well-formed because $P$ preserves well-formedness, and so $\alpha \pi$ is well-formed. So assume that $\pi$ is an input to a basic object or non-access transaction $P$. It suffices to show that $\alpha \pi |P$ is well-formed. There are three cases.

1. $\pi$ is CREATE($T$) for some transaction $T$.
   The scheduler preconditions and Lemma 7 ensure that CREATE($T$) does not appear in $\alpha$.

2. $\pi$ is REPORT _ COMMIT($T,v$) for some transaction $T$ and value $v$.
   Then $\pi$ is an input to transaction parent($T$) = $T'$. The scheduler preconditions and Lemma 7 imply that $\alpha$ contains REQUEST _ COMMIT($T,v$). Well-formedness of $\alpha$ at the non-access transaction $T$ (or at basic object $X$, if $T$ is an access to $X$) implies that $\alpha$ contains CREATE($T$), and the scheduler preconditions and Lemma 7 then require that $\alpha$ contains REQUEST _ CREATE($T$). Also, scheduler preconditions and Lemma 7 imply that COMMIT($T$) occurs in $\alpha$, and thus no ABORT($T$) occurs in $\alpha$. Thus no REPORT _ ABORT($T$) occurs in $\alpha$, by the scheduler preconditions. Well-formedness at $T$ (or at $X$, if $T$ is an access to $X$) implies that no REQUEST _ COMMIT($T,v'$) with $v' \neq v$, occurs in $\alpha$, and therefore by the scheduler preconditions, no REPORT _ COMMIT($T,v'$), $v \neq v$ occurs in $\alpha$.

3. $\pi$ is REPORT _ ABORT($T$) for some transaction $T$.
   Then $\pi$ is an input to transaction parent($T$) = $T'$. The scheduler preconditions and Lemma 7 imply that $\alpha$ contains ABORT($T$) and hence contains REQUEST _ CREATE($T$) but no CREATE($T$). The analysis above shows that this is incompatible with the presence of any REPORT _ COMMIT event for $T$. $\square$

If $\alpha$ is a sequence of serial operations and $T$ is a transaction such that $\alpha$ contains CREATE($T$) but no return event for $T$, we say that $T$ is live in $\alpha$. The following are useful observations:

**Lemma 9:** Let $\alpha$ be a serial schedule, $T$ a transaction live in $\alpha$ and $T'$ an ancestor of $T$. Then $T'$ is live in $\alpha$.

**Lemma 10:** Let $\alpha$ be a serial schedule, and $T$ and $T'$ distinct sibling transactions. If $T$ is live in $\alpha$, then $T'$ is not live in $\alpha$.

A consequence of the two previous lemmas is the following, which states that only related transactions can be live concurrently, in a serial schedule.

**Lemma 11:** Let $\alpha$ be a serial schedule, and $T$ and $T'$ transactions each of which is live in $\alpha$.
Then either $T$ is an ancestor of $T'$ or $T'$ is an ancestor of $T$. 

In order to talk about schedules, we introduce some terms to describe the fate of transactions. Let \( \alpha \) be any sequence of operations. (We will use these same terms later for schedules of R/W Locking systems, so we make the definitions for general sequences.) If \( T \) is a transaction and \( T' \) an ancestor of \( T \), we say that \( T \) is **committed** to \( T' \) in \( \alpha \) if \( \text{COMMIT}(U) \) occurs in \( \alpha \) for every \( U \) which is an ancestor of \( T \) and a proper descendant of \( T' \). If \( T \) and \( T' \) are transactions we say that \( T \) is **visible** to \( T' \) in \( \alpha \) if \( T \) is committed to \( \text{lca}(T,T') \). If \( \pi \) is one of the operations \( \text{CREATE}(T) \), \( \text{REQUEST}_\text{CREATE}(T') \), \( \text{COMMIT}(T') \), \( \text{ABORT}(T') \), \( \text{REPORT}_\text{COMMIT}(T',v') \), \( \text{REPORT}_\text{ABORT}(T',v') \) or \( \text{REQUEST}_\text{COMMIT}(T,v) \) where \( T' \) is a child of \( T \), then we define \( \text{transaction}(\pi) \) to be \( T \). If \( T \) is a non-access transaction then the operations \( \pi \) with \( \text{transaction}(\pi) = T \) are the operations of the automaton \( T \) together with the return operations for children of \( T \). We denote by \( \text{visible}(\alpha,T) \) the subsequence of \( \alpha \) consisting of events \( \pi \) with \( \text{transaction}(\pi) \) visible to \( T \) in \( \alpha \). Notice that every operation occurring in \( \text{visible}(\alpha,T) \) is a serial operation.

We collect here some straightforward consequences of these definitions:

**Lemma 12:** Let \( \alpha \) be a sequence of operations, and \( T, T' \) and \( T'' \) transactions.
1. If \( T \) is an ancestor of \( T' \), then \( T \) is visible to \( T' \) in \( \alpha \).
2. \( T' \) is visible to \( T \) in \( \alpha \) if and only if \( T'' \) is visible to \( \text{lca}(T,T') \) in \( \alpha \).
3. If \( T'' \) is visible to \( T' \) in \( \alpha \) and \( T' \) is visible to \( T \) in \( \alpha \), then \( T'' \) is visible to \( T \) in \( \alpha \).
4. If \( T' \) is a proper descendant of \( T \), \( T'' \) is visible to \( T' \) in \( \alpha \), but \( T'' \) is not visible to \( T \) in \( \alpha \), then \( T'' \) is a descendant of the child of \( T \) which is an ancestor of \( T' \).

**Lemma 13:** Let \( \alpha \) and \( \beta \) be sequences of operations, such that \( \beta \) consists of a subset of the events of \( \alpha \).
1. If transaction \( T \) is visible to transaction \( T' \) in \( \beta \), then \( T \) is visible to \( T' \) in \( \alpha \).
2. If event \( \pi \) is in \( \text{visible}(\beta,T) \), then \( \pi \) is in \( \text{visible}(\alpha,T) \).

**Lemma 14:** Let \( \alpha \) be a sequence of operations, and let \( T \) and \( T' \) be transactions. Then \( \text{visible}(\alpha,T)|T' \) is equal to \( \alpha|T' \) if \( T' \) is visible to \( T \) in \( \alpha \), and is equal to the empty sequence otherwise.

**Lemma 15:** Let \( \alpha \) be a sequence of operations. Let \( T, T' \) and \( T'' \) be transactions such that \( T'' \) is visible to \( T' \) and to \( T \) in \( \alpha \). Then \( T'' \) is visible to \( T' \) in \( \text{visible}(\alpha,T) \).

**Lemma 16:** Let \( T \) be a transaction, and let \( \alpha \pi \) be a sequence of operations, where \( \pi \) is a single event.
1. If transaction \( \pi \) is not visible to \( T \) in \( \alpha \pi \), then \( \text{visible}(\alpha \pi, T) = \text{visible}(\alpha, T) \).
2. If transaction \( \pi \) is visible to \( T \) in \( \alpha \pi \) and if \( \pi \) is not a \( \text{COMMIT} \) event, then \( \text{visible}(\alpha \pi, T) = \text{visible}(\alpha, T) \).
3. If transaction \( \pi \) is visible to \( T \) in \( \alpha \pi \), and \( \pi \) is \( \text{COMMIT}(U) \) then the events in \( \text{visible}(\alpha \pi, T) \) are those visible in \( \alpha \) to either \( T \) or \( U \), together with \( \pi \) itself.

**Lemma 17:** Let \( \alpha \) be a well-formed sequence, and \( T \) any transaction. Then \( \text{visible}(\alpha,T) \) is well-formed.

The next two lemmas are taken from [LM]. (There, they are proved with slightly different definitions, but essentially the same proofs work here.)

**Lemma 18:** Let \( \alpha \) be a serial schedule and \( T \) a transaction. Then \( \text{visible}(\alpha,T) \) is a serial schedule.

**Lemma 19:** Let \( \alpha \) be a serial schedule and \( T \) a transaction. Let \( \beta = \text{visible}(\alpha,T) \). Then \( \gamma = \beta(\alpha - \beta) \) is a serial schedule.
Let $\alpha$ be any sequence of operations. If $T$ is a transaction we say $T$ is an orphan in $\alpha$ if ABORT(U) occurs in $\alpha$ for some ancestor U of $T$. The following lemmas are straightforward.

**Lemma 20:** Let $\alpha$ and $\beta$ be sequences of operations such that $\beta$ consists of a subset of the events in $\alpha$. If a transaction $T$ is not an orphan in $\alpha$ then $T$ is not an orphan in $\beta$.

**Lemma 21:** Let $\alpha$ is a sequence of operations. If $T$ is a transaction that is not an orphan in $\alpha$ and $T'$ is an ancestor of $T$, then $T'$ is not an orphan in $\alpha$.

### 3.5. Serial Correctness

We use serial schedules as the basis of our correctness definition, which was first given in [LM]. Namely, we say that a sequence of operations is *serially correct for a transaction $T$* provided that its projection on $T$ is identical to the projection on $T$ of some serial schedule. That is, the sequence "looks like" a serial schedule to $T$. Later in this paper we will define "R/W Locking systems" and show that their schedules are serially correct for every non-orphan transaction, and in particular that these schedules are serially correct for the root transaction $T_0$.

Motivation for our use of serial schedules to define correctness derives from the simple behavior of the serial scheduler, which determines the sequence of interactions between the transactions and objects. We believe the depth-first traversal of the transaction tree to be a natural notion of correctness which corresponds precisely to the intuition of how nested transaction systems ought to behave. Furthermore, it is a natural generalization of serializability, the correctness condition generally chosen for classical transaction systems. Serial correctness for $T$ is a condition which guarantees to implementors of $T$ that their code will encounter only situations which can arise in serial executions. Correctness for $T_0$ is a special case which guarantees that the external world will encounter only situations which can arise in serial executions.

It would be best if every transaction (whether an orphan or not) saw data consistent with a serial execution. Ensuring this requires a much more intricate scheduler than the simple R/W Locking systems we describe. In [HLMW], we describe and prove correctness of several algorithms for maintaining correctness for orphan transactions.

Our approach is an example of a general technique for studying system algorithms. A simple, intuitive and inefficient algorithm (automaton) is used to specify an acceptable collection of schedules for the system component. The actual system component is more efficient or robust, but provides the same user interface. The user is guaranteed that applications (transactions, in our work) which work well when run with the simple algorithm will work the same way when run with the actual system.
4. Semantic Conditions

In the serial systems to be considered in this paper, accesses are classified as either read or write accesses. In this section, we state the properties which these accesses are required to satisfy. First, we define the fundamental concept of "equieffectiveness" of schedules, which is in turn used to define "transparency" of operations; an operation is said to be transparent if later accesses to the same object return values which are the same as in the situation where the operation did not occur. We then prove certain consequences of these definitions, which will be used in the ensuing proofs. Finally, we use the notion of transparency to specify the precise semantic conditions which read and write accesses must satisfy.

4.1. Equieffective Schedules

We introduce the concept of equieffective schedules of a basic object X, in order to define precisely what schedules we will regard as "essentially" the same. Intuitively, these are schedules which leave the automaton in states which are the same. However, we are really interested in observable behavior, not states, so it is enough that they be indistinguishable by later operations. Formally, given two well-formed sequences α and β of operations of X, we say that α is equieffective to β if for every sequence ϕ of operations of X such that both αϕ and βϕ are well-formed, αϕ is a schedule of X if and only if βϕ is a schedule of X. Notice that if neither α nor β is a schedule of X, then α is trivially equieffective to β. Also, notice that if α is equieffective to β and β is a schedule of X, then α is a schedule of X. In the sense of semantic theory, equieffective schedules pass the same tests, where a test involves determining if a given sequence of operations can occur after the sequence being tested. We limit the tests to sequences which do not violate well-formedness, for technical reasons, because we have not required the objects to behave sensibly if the inputs violate well-formedness. Clearly, α is equieffective to β if and only if β is equieffective to α and in this case we say that α and β are equieffective sequences. We have a restricted form of transitivity:

**Lemma 22:** Let α, β and γ be well-formed sequences of operations of X such that the events in β are a subset of the events in α and the events in γ are a subset of the events in β (perhaps in different orders). If α and β are equieffective and also β and γ are equieffective, then α and γ are equieffective.

**Proof:** Straightforward, using Lemma 4. □

We also have two extension results.

**Lemma 23:** If α and β are equieffective well-formed sequences of operations of X, and ϕ is a sequence of operations of X such that αϕ and βϕ are well-formed, then αϕ and βϕ are equieffective.

**Proof:** This is immediate, since well-formed extensions of αϕ are well-formed extensions of α. □

**Lemma 24:** If α and β are equieffective well-formed sequences of operations of X that contain the same events, and ϕ is a sequence of operations of X such that αϕ is a well-formed schedule of X, then βϕ is a well-formed schedule of X that is equieffective to αϕ.
Proof: Straightforward, by Lemma 5 and Lemma 23, and the definition of equieffective. □

We say that an operation \( \pi \) of basic object X is transparent if for any well-formed schedule \( \alpha \pi \) of X, \( \alpha \pi \) is equieffective to \( \alpha \). Thus, later operations that do not violate well-formedness cannot detect whether \( \pi \) happened. (Notice that we only require \( \pi \) to be undetectable in situations where it can occur, i.e. when \( \alpha \pi \) is a well-formed schedule.)

The following consequences of the definitions above show that certain rearrangements of an object’s schedules are themselves schedules, and are “observably” the same.

**Lemma 25:** Let \( \alpha \beta \) be a well-formed schedule of basic object X, where every operation in \( \beta \) is transparent. Let \( \gamma \) be a sequence of operations of X such that the set of accesses with operations in \( \gamma \) is disjoint from the set of accesses with operations in \( \beta \), and such that \( \alpha \beta \gamma \) is well-formed. Then \( \alpha \gamma \) and \( \alpha \beta \gamma \) are equieffective, and also \( \alpha \gamma \) is a schedule of X if and only if \( \alpha \beta \gamma \) is a schedule of X.

**Proof:** We use induction on the length of \( \beta \). The base case where \( \beta \) is empty is trivial. Suppose then that \( \beta \) has length \( k \) and that the lemma is true for all shorter \( \beta \). Write \( \beta = \beta' \pi \), where \( \beta' \) has length \( k - 1 \). Now, \( \pi \) is transparent so \( \alpha \beta' \pi = \alpha \beta' \) is equieffective to \( \alpha \beta' \) (since \( \alpha \beta' \pi \) is a schedule of X). Since \( \alpha \beta' \pi \gamma \) is well-formed and no operations occurring in \( \gamma \) involve the access of which \( \pi \) is an operation, we have that \( \alpha \beta' \gamma \) is well-formed by Lemma 6. By Lemma 23, \( \alpha \beta' \gamma \) is equieffective to \( \alpha \beta \gamma \). Also, the definition of equieffective allows us to conclude that \( \alpha \beta \gamma \) is a schedule of X if and only if \( \alpha \beta' \gamma \) is a schedule. The induction hypothesis says that \( \alpha \gamma \) is equieffective to \( \alpha \beta' \gamma \), and that \( \alpha \beta' \gamma \) is a schedule of X if and only if \( \alpha \gamma \) is a schedule. Thus \( \alpha \gamma \) is a schedule if and only if \( \alpha \beta \gamma \) is, and Lemma 22 implies that they are equieffective. □

**Lemma 26:** Let \( \alpha \) be a well-formed schedule of basic object X, and S a set of accesses to X such that any operation of a transaction in S that occurs in \( \alpha \) is transparent. Let \( \beta \) be the subsequence of \( \alpha \) obtained by removing all the operations of accesses in S. Then \( \beta \) is a well-formed schedule of X that is equieffective to \( \alpha \).

**Proof:** Repeatedly apply Lemma 25. □

### 4.2. Reordering and Combining Serial Schedules

In this subsection, we describe ways in which serial schedules can be modified and combined to yield other serial schedules. These lemmas are used in the proof of Lemma 48, in Section 6.3. The first generalizes a lemma in [LM], taking into account the special properties of transparent operations. The second is essentially the same as a lemma of [LM]. The proofs are straightforward.

**Lemma 27:** Let \( \alpha \beta_1 \text{COMMIT}(T') \) and \( \alpha \beta_2 \) be two serial schedules and \( T, T' \) and \( T'' \) three transactions such that the following conditions hold:

1. \( T'' \) is a child of \( T' \) and \( T \) is a descendant of \( T'' \) but not of \( T' \),
2. \( \alpha \beta_1 = \text{visible}(\alpha \beta_1, T') \),
3. \( \alpha \beta_2 = \text{visible}(\alpha \beta_2, T) \),
4. \( \alpha = \text{visible}(\alpha \beta_1, T'') = \text{visible}(\alpha \beta_2, T'') \) and
5. if any basic object has an output operation in \( \beta_2 \) then all its operations in \( \beta_1 \) are transparent.

Then \( \alpha \beta_1 \text{COMMIT}(T') \beta_2 \) is a serial schedule.

**Proof:** Note first that if \( T = T'' \), then \( \beta_2 \) is empty and the result is trivial. So assume that
\( T \neq T'' \). Then \( T \) is a descendant of a child \( U \) of \( T'' \), and \( U \neq T' \).

Any event \( \pi \) in \( \alpha_1 \beta_1 \), for which transaction(\( \pi \)) is not a descendant of \( T' \), must be in visible(\( \alpha_1 \beta_1, T'' \)) by Lemma 12. Similarly, any event in \( \alpha_2 \beta_2 \) having transaction which is not a descendant of \( U \), must be in visible(\( \alpha_2 \beta_2, T'' \)). Thus, \( \beta_1 \) and \( \beta_2 \) contain only operations having transactions which are descendants of \( T' \) and \( U \), respectively. Since \( T' \) and \( U \) are distinct siblings, and any operation of a transaction \( P \) has transaction equal to \( P \), it follows that no transaction has operations occurring in both \( \beta_1 \) and \( \beta_2 \).

We proceed by induction on prefixes of \( \alpha_1 \beta_1 \text{COMMIT}(T') \beta_2 \). Let \( \alpha' \phi \) be a prefix of \( \alpha_1 \beta_1 \text{COMMIT}(T') \beta_2 \), with \( \alpha' \) a serial schedule and \( \phi \) an event. We use \( \alpha_1 \beta_1 \text{COMMIT}(T') \) as the basis, since \( \alpha_1 \beta_1 \text{COMMIT}(T') \) is a serial schedule by assumption. So assume that \( \alpha' = \alpha_1 \beta_1 \text{COMMIT}(T') \beta' \phi \) for some prefix \( \beta' \) of \( \beta_2 \). There are three cases, depending on whether \( \phi \) is an output of a basic object, of a non-access transaction, or of the serial scheduler.

Suppose that \( \phi \) is an output of a basic object \( X \). By assumption, every operation of \( \beta_1 |X \) is transparent, and since \( \text{COMMIT}(T') \) does not occur at \( X \), so is every operation of \( \beta_1 \text{COMMIT}(T') |X \). We saw above that the set of accesses with operations in \( \beta_1 \) and the set of accesses with operations in \( \beta_2 \) are disjoint (being respectively descendants of \( T' \) and of \( U \)). By Lemma 6, \( \alpha_1 \beta_1 \text{COMMIT}(T') \beta' \phi |X \) is well-formed, and we may deduce by Lemma 25 that \( \alpha_1 \beta_1 \text{COMMIT}(T') \beta' \phi |X \) is a schedule of \( X \), since \( \alpha_1 \beta_1 \phi |X \) is a schedule. Now the result follows by Lemma 1.

Suppose that \( \phi \) is an output operation of a non-access transaction \( P \). Then \( \beta_1 \text{COMMIT}(T') \) contains no operations of \( P \). Thus, \( \alpha' \phi |P = \alpha_1 \beta_1 \phi |P \), which is a prefix of \( \alpha_1 \beta_2 |P \), which is a schedule of \( P \) since \( \alpha_2 \) is a serial schedule. Thus, \( \alpha' \phi |P \) is a schedule of \( P \). The result follows by Lemma 1.

Finally, suppose \( \phi \) is an output of the serial scheduler. Then \( \phi \) has transaction \( V \) for some descendant \( V \) of \( U \). Let \( s \) be the (uniquely defined) state of the serial scheduler after \( \alpha' \), and let \( s' \) be the state of the serial scheduler after \( \alpha' \). Then the following relationships hold between \( s \) and \( s' \):

1. \( V \in s' \text{.create_requested} \) \iff \( V \in s \text{.create_requested} \)
2. \( \text{children}(V) \cap s' \text{.create_requested} \subseteq s' \text{.returned} \)
3. \( \text{children}(V) \cap s \text{.create_requested} \subseteq s \text{.returned} \)
4. \( (V, v) \in s' \text{.commit_requested} \)
5. \( V \in s' \text{.committed} \)
6. \( V \in s' \text{.aborted} \)
7. \( V \notin s' \text{.returned} \)
8. \( \text{siblings}(V) \cap s' \text{.created} \subseteq s' \text{.returned} \)

Since any event in \( \beta_1 \) has transaction equal to some descendant of \( T' \), and the operations REQUEST\_CREATE(\( V \)), CREATE(\( V \)), ABORT(\( V \)), REQUEST\_COMMIT(\( V, v \)), COMMIT(\( V \)), and REQUEST\_CREATE(\( V' \)), ABORT(\( V' \)), COMMIT(\( V' \)) for \( V \) a child of \( V \), all have transaction equal to \( V \) or parent(\( V \)), neither of which is a descendant of \( T' \), the first six biconditionals are immediate from Lemma 7. If \( V \) is a proper descendant of \( U \), the last biconditional also follows. It remains to show that \( \text{siblings}(U) \cap s' \text{.created} \subseteq s' \text{.returned} \), and any sibling of \( U \) created in \( \alpha' \) is created in \( \alpha' \), and
the only sibling of U created in α' and not αβ' is T', and T' ∈ s.returned. Thus, the claims are true.

Since φ is enabled in s', the claims above imply that φ is also enabled in s. The result follows by Lemma 1. □

Lemma 28: Let αABORT(T') and αβ be two serial schedules, and let T, T' and T'' be transactions, such that the following conditions hold:

1. T' is a child of T'' and T is a descendant of T'' but not of T',
2. αβ = visible(αβ, T), and
3. α = visible(α,T'') = visible(αβ,T'').

Then αABORT(T')β is a serial schedule.

4.3. Semantics of Read Accesses

Finally, we are ready to state the conditions to be satisfied by read and write accesses. Namely, we require that each basic object X satisfy the following conditions.

Semantic Conditions:

(i) Every CREATE(T) operation is transparent.
(ii) For any α₁ and α₂ for which α₁CREATE(T)α₂ and α₁α₂CREATE(T) are both well-formed schedules of X, they are equieffective schedules.
(iii) Every REQUEST_COMMIT(T,v) operation, for T a read access, is transparent.

Condition (i) means that whether or not an access was created is invisible to other accesses. Condition (ii) means that later operations cannot detect when an access was created. Condition (iii) means that later operations cannot determine whether or not a REQUEST_COMMIT operation for a read access has occurred. The third condition captures the fundamental feature of read accesses that allows Moss' algorithm, as given in the construction of R/W Locking objects in Section 5.1, to work. In contrast, the first two conditions are a convenience, used to avoid explicitly reordering schedules of the R/W locking objects. Note that we make no assumption about the semantics of REQUEST_COMMIT operations for write accesses, and so it is legitimate to designate all accesses as writes. If this is done, Moss' algorithm as given in this paper degenerates into exclusive locking.

An example of a basic object satisfying these conditions would have as its state a set of transactions, called "pending", and an instance of an abstract data type. The input operation CREATE(T) would simply add T to pending. At any time, a transaction T in pending could be chosen, and the corresponding function applied to the instance of the abstract data type, yielding return value v, and a possibly altered instance of the abstract type. T would be removed from pending, the new instance would replace the old one in the state of the basic object, and REQUEST_COMMIT(T,v) would occur. (The whole sequence from choosing T to the output is an atomic step of the basic object.)
The following lemma combines all the information in the semantic conditions to give a simple sufficient condition for proving that schedules are equieffective. This test is used throughout this paper. Given a sequence \( \alpha \) of operations of \( X \), define \( \text{write}(\alpha) \) to be the subsequence of \( \alpha \) consisting of the REQUEST\_COMMIT(\(T,v\)) events for write accesses \( T \). If \( \alpha \) and \( \beta \) are sequences of operations of \( X \) and \( \text{write}(\alpha) = \text{write}(\beta) \) then we say that \( \alpha \) and \( \beta \) are write-equal. This is clearly an equivalence relation on sequences of operations of \( X \).

**Lemma 29:** Let \( \alpha \) and \( \beta \) be well-formed schedules of \( X \) that are write-equal. Then \( \alpha \) and \( \beta \) are equieffective.

**Proof:** Suppose \( \phi \) is a sequence of operations of \( X \) such that \( \alpha \phi \) and \( \beta \phi \) are both well-formed. We must prove that \( \beta \phi \) is a schedule of \( X \) if and only if \( \alpha \phi \) is a schedule of \( X \). Consider the set \( A \) of accesses to \( X \) that is the union of the set of write accesses for which a REQUEST\_COMMIT operation occurs in \( \alpha \) (and so also in \( \beta \)) and the set of accesses that are pending in both \( \alpha \) and \( \beta \). Let \( \alpha' \) denote the subsequence of \( \alpha \) consisting of the events of accesses in \( A \). Similarly let \( \beta' \) denote the subsequence of \( \beta \) consisting of the events of accesses in \( A \). Since \( \alpha' \) is obtained from \( \alpha \) by removing all the operations of accesses not in \( A \), and all such operations are transparent (by conditions (i) and (iii)), by Lemma 26, we deduce that \( \alpha' \) is a well-formed schedule of \( X \) equieffective to \( \alpha \). Similarly \( \beta' \) is a well-formed schedule equieffective to \( \beta \). Also, since \( \alpha' \) can be formed from \( \beta' \) by moving CREATE events, we deduce from condition (ii), Lemma 24 and Lemma 22 that \( \alpha' \) and \( \beta' \) are equieffective. Since both \( \alpha \phi \) and \( \beta \phi \) are well-formed, by Lemma 3 any event in \( \phi \) must be either an operation of an access with no operations in \( \alpha \) or \( \beta \), or else a REQUEST\_COMMIT for an access that is pending in both \( \alpha \) and \( \beta \). In any case, \( \alpha' \phi \) and \( \beta' \phi \) must be well-formed. Therefore \( \alpha \phi \) is a schedule of \( X \) if and only if \( \alpha' \phi \) is a schedule, which is true if and only if \( \beta' \phi \) is a schedule and so if and only if \( \beta \phi \) is a schedule of \( X \). \( \Box \)

5. R/W Locking Systems

A R/W Locking system of a given system type is composed of transactions, a generic scheduler, and R/W Locking objects. The non-access transactions are modelled by the same automata as in the serial system, but the generic scheduler has much more freedom in scheduling transactions than the serial scheduler, and R/W Locking objects follow the algorithm of [Mo] in maintaining locking and state restoration data that basic objects do not need.

5.1. R/W Locking objects

In this section, we define, for each basic object \( X \), a R/W Locking object \( M(X) \), which provides a resilient lock-managing variant of \( X \). It receives operation invocations and responds like \( X \), and also receives information about the fate of transactions so that it can maintain its locking and state restoration data. A R/W Locking object combines the features of the resilient object and the lock manager of [LM], where, as in many database management systems, the recovery and concurrency control are performed separately. Combining these features, as we do here, eliminates some redundancy in maintaining information about the fate of transactions.

\( M(X) \) has the following operations.
Input Operations:
CREATE(T), for T an access to X
INFORM_COMMIT_AT(X)OF(T), T ≠ T₀
INFORM_ABORT_AT(X)OF(T), T ≠ T₀

Output Operations:
REQUEST_COMMIT(T,v), for T an access to X

We give a recursive definition for well-formedness of schedules of object M(X). Namely, the empty schedule is well-formed. Also, if α = α'π is a sequence of operations of object X, then α is well-formed provided that α' is well-formed and the following hold.

- If π is CREATE(T), then
  (i) there is no CREATE(T) event in α'.

- If π is a REQUEST_COMMIT for T, then
  (i) there is no REQUEST_COMMIT event for T in α', and
  (ii) CREATE(T) occurs in α'.

- If π is INFORM_COMMIT_AT(X)OF(T), then
  (i) there is no INFORM_ABORT_AT(X)OF(T) event in α', and
  (ii) if T is an access to X, then a REQUEST_COMMIT event for T occurs in α'.

- If π is INFORM_ABORT_AT(X)OF(T), then
  (i) there is no INFORM_COMMIT_AT(X)OF(T) event in α'.

A state s of M(X) consists of the following five components: s.write-lockholders, s.read-lockholders, s.create_requested, and s.run, which are sets of transactions, and s.map, which is a function from write-lockholders to states of the basic object X. We say that a transaction in write-lockholders holds a write-lock, and similarly that a transaction in read-lockholders holds a read-lock. We say two locks conflict if they are held by different transactions and at least one is a write-lock. The initial states of M(X) are those in which write-lockholders = {T₀} and map(T₀) is an initial state of the basic object X, and the other components are empty. The transition relation of M(X) is given by all triples (s',π,s) satisfying the following pre- and postconditions, given separately for each π. As before, any component of s not mentioned in the postconditions is the same in s as in s'.

CREATE(T), T an access to X
Postcondition:
  s.create_requested = s'.create_requested ∪ {T}

INFORM_COMMIT_AT(X)OF(T), T ≠ T₀
Postcondition:
  if T ∈ s'.write-lockholders then
    begin
      s.write-lockholders = (s'.write-lockholders - {T}) ∪ {parent(T)}
      s.map(U) = s'.map(U) for U ∈ s.write-lockholders - {parent(T)}
      s.map(parent(T)) = s'.map(T)
    end
  if T ∈ s'.read-lockholders then
begin
  s'.read-lockholders = (s'.read-lockholders - \{T\}) \cup \{\text{parent}(T)\}
end

INFORM\_ABORT\_AT(X)OF(T), T \neq T_0

Postcondition:
  s'.write-lockholders = s'.write-lockholders - \text{descendants}(T)
  s'.read-lockholders = s'.read-lockholders - \text{descendants}(T)
  s.map(U) = s'.map(U) \text{ for all } U \in \text{s.write-lockholders}

REQUEST\_COMMIT(T,v) for T a write access to X

Precondition:
  T \in s'.create\_requested - s'.run
  s'.write-lockholders \cup s'.read-lockholders \subseteq \text{ancestors}(T)
  \text{there are states } t, t' \text{ of basic object } X \text{ so that}
  \{(s'.map(\text{least(s'.write-lockholders))),\text{CREATE}(T),t)\}
  \text{and } (t,\text{REQUEST\_COMMIT}(T,v),t')
  \text{are in the transition relation of basic object } X

Postcondition:
  s.run = s'.run \cup \{T\}
  s'.write-lockholders = s'.write-lockholders \cup \{T\}
  s.map(U) = s'.map(U) \text{ for all } U \in \text{s.write-lockholders} - \{T\}
  s.map(T) = t'

REQUEST\_COMMIT(T,v) for T a read access to X

Precondition:
  T \in s'.create\_requested - s'.run
  s'.write-lockholders \subseteq \text{ancestors}(T)
  \text{there are states } t, t' \text{ of basic object } X \text{ so that}
  \{(s'.map(\text{least(s'.write-lockholders))),\text{CREATE}(T),t)\}
  \text{and } (t,\text{REQUEST\_COMMIT}(T,v),t')
  \text{are in the transition relation of basic object } X

Postcondition:
  s.run = s'.run \cup \{T\}
  s.read-lockholders = s'.read-lockholders \cup \{T\}

It is clear that a R/W Locking object preserves well-formedness.

The operation of a R/W Locking object should be clear from the pre- and postconditions above. Indeed, we feel that the clarity and lack of ambiguity in describing the algorithm in this way is a significant feature of our method, since informal descriptions of algorithms often omit significant details.

When an access transaction is created, it is added to the set create-requested. A response containing return value v to an access T can be returned only if the access has been requested but not yet responded to, every holder of a conflicting lock is an ancestor of T, and v is a value that can be returned by basic object X in the response to T from a state, obtained by performing CREATE(T) in the state that is the
value of map at the least member of write-lockholders. When a response is given, the access transaction is added to run and granted the appropriate lock, and if the transaction is a write access, the resulting state is stored as map(T). If the transaction is a read access, no change is made to the stored state of the basic object X, i.e. to map.

When a R/W Locking object is informed of the abort of a transaction, it removes all locks held by descendants of the transaction. When it is informed of a commit, it passes any locks held by the transaction to the parent, and also passes the version stored in map, if there is one.\(^8\)

We introduce some terms to describe what M(X) knows about commits and aborts of transactions. If \(\alpha\) is a sequence of operations of M(X), T is an access to X, and \(T'\) is an ancestor of T, we say that T is committed at X to \(T'\) in \(\alpha\) if \(\alpha\) contains a subsequence \(\beta\) consisting of an \texttt{INFORM\_COMMIT\_AT}(X)OF(U) event for every U that is an ancestor of T and a proper descendant of \(T'\), arranged in ascending order (so the \texttt{INFORM\_COMMIT} for parent(U) is preceded by that for U).

If \(\alpha\) is a well-formed sequence of operations of M(X), T is an access to X, and \(T'\) is any transaction, we say that T is visible at X to \(T'\) in \(\alpha\) if T is committed at X to \(T'\) to lca(T,T'). We denote by \(\text{visible}_X(\alpha,T)\) the subsequence of \(\alpha\) that consists of operations of X whose transactions are visible at X to T in \(\alpha\). It is clear that \(\text{visible}_X(\alpha,T)\) is a well-formed sequence of operations of basic object X. We say that a transaction T is an orphan at X in \(\alpha\) if \texttt{INFORM\_ABORT\_AT}(X)OF(U) occurs in \(\alpha\) for some ancestor U of T.

We collect here some obvious facts about visibility at X of transactions.

**Lemma 30:** Let \(\alpha\) be a sequence of operations of M(X) and \(\beta\) a sequence consisting of a subset of the events of \(\alpha\). Let T be an access to X and \(T'\) a transaction. If T is visible at X to \(T'\) in \(\beta\) then T is visible at X to \(T'\) in \(\alpha\).

**Lemma 31:** Let \(\alpha\) be a sequence of operations of M(X), and let T and \(T'\) be accesses to X, and \(T''\) a transaction. If T is visible at X to \(T'\) in \(\alpha\), and \(T'\) is visible at X to \(T''\) in \(\alpha\), then T is visible at X to \(T''\) in \(\alpha\).

**Lemma 32:** Let \(\alpha\) be a well-formed sequence of operations of M(X), and let T be an access to X and \(T'\) a transaction. If T is visible at X to \(T'\) in \(\alpha\), and \(T'\) is not an orphan at X in \(\alpha\), then T is not an orphan at X in \(\alpha\).

**Lemma 33:** Let \(\alpha = \alpha'\pi\) be a well-formed sequence of operations of M(X).
1. If \(\pi\) is a \texttt{CREATE}(T') or \texttt{REQUEST\_COMMIT}(T',v) event, and \(T' \neq T'\), then \(\text{visible}_X(\alpha,T) = \text{visible}_X(\alpha',T)\).
2. If \(\pi\) is a \texttt{CREATE}(T) or \texttt{REQUEST\_COMMIT}(T,v) event, then \(\text{visible}_X(\alpha,T) = \text{visible}_X(\alpha',T)\).
3. If \(\pi\) is \texttt{INFORM\_COMMIT\_AT}(X)OF(T') with parent(T') an ancestor of T, then \(\text{visible}_X(\alpha,T)\) consists of the events of \(\alpha'\) that are visible at X to either T or \(T'\) in \(\alpha'\).

---

\(^8\) If the reader wishes to compare our version of the algorithm with that in [Mo], the following may be useful: Moss gives the name \"the associated state\" for object X and transaction T to what we call s.map(T') where T' is the least ancestor of T in s.write-lockholders, and he calls s.map(least[s.write-lockholders]) \"the current state\" of X. Also, he removes a read-lock when the owner also holds a write-lock (this is an optimization that does not affect the correctness proof). Moss also allows internal transactions to directly access objects, whereas we only allow leaf transactions perform data access.
4. If \( \pi \) is \textsc{Inform-Commit-At}\((X)\text{Of}(T')\) with parent\((T')\) not an ancestor of \( T \), or if \( \pi \) is \textsc{Inform-Abort-At}\((X)\text{Of}(T')\), then visible\(_X\)(\(\alpha, T\)) = visible\(_X\)(\(\alpha', T\)).

Here are some simple facts about the state of \( M(X) \) after a schedule \( \alpha \).

**Lemma 34:** Let \( \alpha \) be a schedule of \( M(X) \), and \( s \) a state of \( M(X) \) reached by applying \( \alpha \) to an initial state. Suppose \( T \in s\text{-write-lockholders} \) and \( T' \in s\text{-read-lockholders} \cup s\text{-write-lockholders} \). Then either \( T \) is an ancestor of \( T' \) or else \( T' \) is an ancestor of \( T \).

**Lemma 35:** Let \( \alpha \) be a well-formed schedule of \( M(X) \), and \( s \) a state of \( M(X) \) reached by applying \( \alpha \) to an initial state. Let \( T \) be an access to \( X \) such that \textsc{Request-Commit}\((T, v)\) occurs in \( \alpha \) and \( T \) is not an orphan at \( X \) in \( \alpha \), and let \( T' \) be the highest ancestor of \( T \) such that \( T \) is committed at \( X \) to \( T' \) in \( \alpha \). Then if \( T \) is a write access, \( T' \) must be a member of \( s\text{-write-lockholders} \), while if \( T \) is a read access, \( T' \) must be a member of \( s\text{-read-lockholders} \).

Given any well-formed sequence \( \beta \) of operations of \( M(X) \) let \( \text{essence}(\beta) \) denote the sequence obtained from \( \text{write}(\beta) \) by placing a \textsc{Create}\((U)\) event immediately preceding a \textsc{Request-Commit}\((U, u)\) event. Since \( \beta \) is well-formed, \( \text{essence}(\beta) \) consists of a subset of the events of \( \beta \) and is well-formed. Clearly \( \beta \) and \( \text{essence}(\beta) \) are write-equal.

The following lemma shows how the results of operations visible at \( X \) to \( T \) are recorded in the state of \( M(X) \).

**Lemma 36:** Let \( \alpha \) be a well-formed schedule of \( M(X) \) and \( s \) a state of \( M(X) \) reached by applying \( \alpha \) to an initial state. If \( T \) is a transaction that is not an orphan at \( X \) in \( \alpha \), then \( \beta = \text{essence}(\text{visible}\(_X\)(\(\alpha, T\))) \) is a well-formed schedule of the basic object \( X \). Furthermore, when \( \beta \) is applied to an initial state of \( X \), it can leave \( X \) in the state \( s\text{-map}(T') \) where \( T' \) is the least ancestor of \( T \) such that \( T' \in s\text{-write-lockholders} \).

**Proof:** We use induction on the length of \( \alpha \). The basis case is trivial, so let \( \alpha = \alpha' \pi \). Let \( s' \) denote a state of \( M(X) \) after applying \( \alpha' \) such that \((s', \pi, s)\) is a step of \( M(X) \). There are five cases.

1. \( \pi \) is \textsc{Create}\((U)\) for an access \( U \) to \( X \). If \( U = T \) then \text{visible}\(_X\)(\(\alpha, T\)) = \text{visible}\(_X\)(\(\alpha', T\))\(\pi\), while otherwise \text{visible}\(_X\)(\(\alpha, T\)) = \text{visible}\(_X\)(\(\alpha', T\)). In either case \( \beta = \text{essence}(\text{visible}\(_X\)(\(\alpha, T\))) = \text{essence}(\text{visible}\(_X\)(\(\alpha', T\))). \) Also \( s'\text{-write-lockholders} = s\text{-write-lockholders} \) and \( s'\text{-map} = s\text{-map} \), so the induction hypothesis implies that \( \beta \) is a well-formed schedule of \( X \) that can leave \( X \) in state \( s'\text{-map}(T') = s\text{-map}(T') \) when applied to an initial state.

2. \( \pi \) is \textsc{Request-Commit}\((U, v)\) for \( U \) a read access to \( X \). If \( U = T \) then \text{visible}\(_X\)(\(\alpha, T\)) = \text{visible}\(_X\)(\(\alpha', T\))\(\pi\), while otherwise \text{visible}\(_X\)(\(\alpha, T\)) = \text{visible}\(_X\)(\(\alpha', T\)). In either case \( \beta = \text{essence}(\text{visible}\(_X\)(\(\alpha, T\))) = \text{essence}(\text{visible}\(_X\)(\(\alpha', T\))). \) Also \( s'\text{-write-lockholders} = s\text{-write-lockholders} \) and \( s'\text{-map} = s\text{-map} \), so the induction hypothesis implies that \( \beta \) is a well-formed schedule of \( X \) that can leave \( X \) in state \( s'\text{-map}(T') = s\text{-map}(T') \) when applied to an initial state.

3. \( \pi \) is \textsc{Request-Commit}\((U, v)\) for \( U \) a write access to \( X \). We consider separately the cases \( U = T \) and \( U \neq T \). If \( U = T \) then \( T \in s\text{-write-lockholders} \) so \( T' = T \). Let \( T'' \) denote the least ancestor of \( T \) in \( s'\text{-write-lockholders} \). Let \( \beta'' = \text{essence}(\text{visible}\(_X\)(\(\alpha', T\))). \) By the induction hypothesis, \( \beta'' \) is a
well-formed schedule of X that can leave X in the state $s'.map(T'')$ when applied to an initial state. Now $\beta = \beta' CREATE(U) \pi$; by the definition of $M(X)$, $\beta' CREATE(U) \pi$ is a (well-formed) schedule of X, and applied to an initial state of X it can leave X in the state $s.map(T)$. If $U \neq T$, $s'.write-lockholders = s.write-lockholders - \{U\}$, so $T'$ is also the least ancestor of $T$ in $s'.write-lockholders$, and $s'.map(T') = s.map(T')$. Also, $\text{visible}_X(\alpha, T) = \text{visible}_X(\alpha', T)$ so $\beta = \text{essence}(\text{visible}_X(\alpha, T)) = \text{essence}(\text{visible}_X(\alpha', T))$. The desired result follows immediately from the inductive hypothesis.

(4) $\pi$ is $\text{INFORM\_COMMIT\_AT}(X)OF(U)$
The discussion is divided into subcases, depending on the relation of $T$ and $U$ in the transaction tree.

(i) $U$ is an ancestor of $T$.
Now $\text{visible}_X(\alpha, T) = \text{visible}_X(\alpha', T)$, so $\beta = \text{essence}(\text{visible}_X(\alpha', T))$. If $U$ is the least ancestor of $T$ in $s'.write-lockholders$ then by the definition of $M(X)$, $T'$ must be parent(U) and $s.map(T') = s'.map(U)$, while if U is not the least ancestor of $T$ in $s'.write-lockholders$ then $T'$ must be the least ancestor of $T$ in $s'.write-lockholders$ and $s.map(T') = s'.map(T')$. In either case, $s.map(T')$ is $s'.map(T'')$, where $T''$ is the least ancestor of $T$ in $s'.write-lockholders$. The desired result follows immediately from the inductive hypothesis.

(ii) $U$ is not an ancestor of $T$, but parent(U) is an ancestor of $T$.
Here we give separate arguments, depending on whether $U$ is in $s'.write-lockholders$ or not. If $U \in s'.write-lockholders$ then Lemma 34 implies that no ancestor of $T$ that is a strict descendant of parent(U) can be in $s'.write-lockholders$. The definition of $M(X)$ therefore shows that $T' = \text{parent}(U)$ and that $s.map(T') = s'.map(U)$. Also we note that $\text{visible}_X(\alpha', U)$ is write-equal to $\text{visible}_X(\alpha, T)$, since any write access (for which a $\text{REQUEST\_COMMIT}$ event occurs in $\alpha$) that is committed at X to an ancestor of $T$ in $\alpha'$ must be committed at X to parent(U) in $\alpha'$ and thus visible at X to U in $\alpha$ (otherwise by Lemma 35 some ancestor of $T$ that is a proper descendant of parent(U) would be in $s'.write-lockholders$). Thus $\beta = \text{essence}(\text{visible}_X(\alpha, T)) = \text{essence}(\text{visible}_X(\alpha', U))$. By the induction hypothesis, $\beta$ is a well-formed schedule of X which, when applied to an initial state of X, can leave X in state $s'.map(U) = s.map(T')$. On the other hand, if $U \notin s'.write-lockholders$ then $s'.write-lockholders = s'.write-lockholders$ and $s.map = s'.map$. Also $\text{visible}_X(\alpha', T)$ is write-equal to $\text{visible}_X(\alpha, T)$. This is true because any operation visible at X to T in $\alpha$ is either visible at X to $T$ in $\alpha'$ or else is the operation of an access that is committed at X to U in $\alpha'$, and any write access (for which a $\text{REQUEST\_COMMIT}$ event occurs in $\alpha'$) that is committed at X to U in $\alpha'$ must be committed at X to parent(U) (and hence visible at X to T) in $\alpha'$, by Lemma 35 and the assumption that $U \notin s'.write-lockholders$. Thus $\beta = \text{essence}(\text{visible}_X(\alpha, T)) = \text{essence}(\text{visible}_X(\alpha', T))$. By the induction hypothesis, $\beta$ is a well-formed schedule of X that, when applied to an initial state of X, can leave X in the state $s'.map(T') = s.map(T')$.

(iii) parent(U) is not an ancestor of T.
Then $\text{visible}_X(\alpha, T) = \text{visible}_X(\alpha', T)$, so $\beta = \text{essence}(\text{visible}_X(\alpha', T))$. Also $T'$ is the least ancestor of $T$ in $s'.write-lockholders$ and $s.map(T') = s.map(T')$. The desired result follows immediately from the inductive hypothesis.

(5) $\pi$ is $\text{INFORM\_ABORT\_AT}(X)OF(U)$.
Then $\text{visible}_X(\alpha, T) = \text{visible}_X(\alpha', T)$, so $\beta = \text{essence}(\text{visible}_X(\alpha, T)) = \text{essence}(\text{visible}_X(\alpha', T))$. Also since $T$ is not an orphan at X, $U$ is not an ancestor of $T$. Thus $T'$ is the least ancestor of
T in s'.write-lockholders and s'.map(T') = s.map(T'). The desired result follows immediately from the inductive hypothesis. □

A consequence of this is the following lemma, which explains a sense in which M(X) is a resilient variant of the basic object X.

**Lemma 37:** Let α be a well-formed schedule of M(X) and T a transaction that is not an orphan at X in α. Then visible_\(X(\alpha, T)\) is a well-formed schedule of the basic object X.

**Proof:** We prove that visible_\(X(\alpha, T)\) is a schedule of X by induction on the prefixes of visible_\(X(\alpha, T)\). The base case is trivial. So consider an event π in visible_\(X(\alpha, T)\), and the prefix β of visible_\(X(\alpha, T)\) ending with π. Let β = β'π. By the inductive hypothesis β' is a well-formed schedule of X. We must show that β is well-formed and that it is a schedule of X. Since π is visible at X to T in α, so is any operation of the same access. Since α is well-formed, it follows that all the requirements of operations' presence or absence in β are satisfied, to permit us to deduce that β is well-formed from Lemma 3. If π is a CREATE event it follows from the Input Condition on all I/O automata that π is enabled after β', and thus that β is a schedule of X, so suppose that π is REQUEST_COMMIT(U,u). Consider visible_\(X(\gamma', U)\) where γ = γ'π is the prefix of α ending with π. Let s' denote the state of M(X) immediately before π occurs, and let U' denote the least ancestor of U in s'.write-lockholders. By Lemma 36, φ = essence(visible_\(X(\gamma', U)\)) is a well-formed schedule of X that can leave X in the state s'.map(U') when applied to an initial state. By the preconditions for the operation π of M(X), φCREATE(U)π is a schedule of X, which is well-formed since no operations of the access U occur in the well-formed sequence φ.

We now show that β' and φCREATE(U) are equieffective. Since each is a well-formed schedule of X, it suffices by Lemma 29 to show that they are write-equal. Now φCREATE(U) and visible_\(X(\gamma', U)\) are write-equal, so we need only show that visible_\(X(\gamma', U)\) and β' are write-equal. Since U is visible at X to T in α, any access visible at X to U in γ' must be visible at X to T in α, so the events in visible_\(X(\gamma', U)\) are a subset of the events in β'. Now, by the preconditions for π as an operation of M(X) every element of s'.write-lockholders is an ancestor of U. So if REQUEST_COMMIT(V,v) occurs in β' for a write access V to X, then Lemma 35 implies that V must be committed at X to lca(V,U) in γ' (since V is not an orphan at X in γ', as it is visible at X to T in α). Thus V is visible at X to U in γ', so REQUEST_COMMIT(V,v) occurs in visible_\(X(\gamma', U)\). Also all REQUEST_COMMIT events for write accesses in visible_\(X(\gamma', U)\) occur in the same order as in α, and similarly the REQUEST_COMMIT events for write accesses in β' occur in the same order as in α. Thus visible_\(X(\gamma', U)\) and β' are write-equal, completing the proof that φCREATE(U) and β' are equieffective.

Since φCREATE(U)π is a well-formed schedule of X and β = β'π is well-formed, the definition of equieffective implies that β is a well-formed schedule of X, as required. Thus, by induction, visible_\(X(\alpha, T)\) is a well-formed schedule of X. □

### 5.2. Generic Scheduler

The generic scheduler is a very nondeterministic automaton. It passes requests for the creation of subtransactions or accesses to the appropriate recipient, passes responses back to the caller and informs objects of the fate of transactions, but it may delay such messages for arbitrary lengths of time or
unilaterally decide to abort a subtransaction which has been created. Moss [Mo] devotes considerable effort to describing a distributed implementation of the scheduler that copes with communication failures and loss of system information due to crashes, yet still commits a subtransaction whenever possible. These concerns are orthogonal to the correctness of the data management algorithms and we do not address them here.\footnote{The generic scheduler is very similar to the weak concurrent controller of [LM]. It differs slightly in the names of its operations, in the separation of return and report operations, and in the conditions under which CREATE operations are permitted to occur.}

The generic scheduler has nine operations:

Input Operations:
- REQUEST_CREATE(T)
- REQUEST_COMMIT(T,v)

Output Operations:
- CREATE(T)
- COMMIT(T), T \neq T_0
- ABORT(T), T \neq T_0
- REPORT_COMMIT(T,v), T \neq T_0
- REPORT_ABORT(T), T \neq T_0
- INFORM_COMMIT_AT(X)OF(T), T \neq T_0
- INFORM_ABORT_AT(X)OF(T), T \neq T_0

These play the same roles as in the serial scheduler, except for the INFORM_COMMIT and INFORM_ABORT operations, which pass information about the fate of transactions to the R/W Locking objects.

Each state s of the generic scheduler consists of six sets: s.create_requested, s.created, s.commit_requested, s.committed, s.aborted and s.returned. The set s.commit_requested is a set of (transaction,value) pairs, and the others are sets of transactions. All are empty in the initial state except for create_requested, which is \{T_0\}.

The operations are defined by pre- and postconditions as follows:

REQUEST_CREATE(T)
Postcondition:
\[ s.create_requested = s'.create_requested \cup \{T\} \]

REQUEST_COMMIT(T,v)
Postcondition:
\[ s.commit_requested = s'.commit_requested \cup \{(T,v)\} \]

CREATE(T), T a transaction
Precondition:
\[ T \in s'.create_requested \setminus s'.created \]
Postcondition:
s.created = s'.created ∪ \{T\}

\textbf{COMMIT(T), }T \not\in T_0
Precondition:
\begin{itemize}
\item \((T,v) \in s'.\text{commit\_requested}\) for some \(v\)
\item \(T \not\in s'.\text{returned}\)
\item \text{children}(T) \cap s'.\text{create\_requested} \subseteq s'.\text{returned}
\end{itemize}
Postcondition:
\begin{itemize}
\item s.committed = s'.committed ∪ \{T\}
\item s.returned = s'.returned ∪ \{T\}
\end{itemize}

\textbf{ABORT(T), }T \not\in T_0
Precondition:
\begin{itemize}
\item \(T \in s'.\text{create\_requested} - s'.\text{returned}\)
\end{itemize}
Postcondition:
\begin{itemize}
\item s.aborted = s'.aborted ∪ \{T\}
\item s.returned = s'.returned ∪ \{T\}
\end{itemize}

\textbf{REPORT\_COMMIT(T,v), }T \not\in T_0
Precondition:
\begin{itemize}
\item \(T \in s'.\text{committed}\)
\item \((T,v) \in s'.\text{commit\_requested}\)
\end{itemize}

\textbf{REPORT\_ABORT(T), }T \not\in T_0
Precondition:
\begin{itemize}
\item \(T \in s'.\text{aborted}\)
\end{itemize}

\textbf{INFORM\_COMMIT\_AT(X)OF(T), }T \not\in T_0
Precondition:
\begin{itemize}
\item \(T \in s'.\text{committed}\)
\end{itemize}

\textbf{INFORM\_ABORT\_AT(X)OF(T), }T \not\in T_0
Precondition:
\begin{itemize}
\item \(T \in s'.\text{aborted}\)
\end{itemize}

The following lemma relates the state of the generic scheduler to its schedule.

\textbf{Lemma 38:} Let \(\alpha\) be a schedule of the generic scheduler, and let \(s\) be a state which can result from applying \(\alpha\) to the initial state \(s_0\). Then the following conditions are true.

1. \(T\) is in \(s.\text{create\_requested}\) exactly if \(\alpha\) contains a \text{REQUEST\_CREATE}(T) event.
2. \(T\) is in \(s.\text{created}\) exactly if \(\alpha\) contains a \text{CREATE}(T) event.
3. \((T,v)\) is in \(s.\text{commit\_requested}\) exactly if \(\alpha\) contains a \text{REQUEST\_COMMIT}(T,v) event.
4. \(T\) is in \(s.\text{committed}\) exactly if \(\alpha\) contains a \text{COMMIT}(T) event.
5. \(T\) is in \(s.\text{aborted}\) exactly if \(\alpha\) contains a \text{ABORT}(T) event.
6. \(s.\text{returned} = s.\text{committed} \cup s.\text{aborted}\).
7. \(s.\text{committed} \cap s.\text{aborted} = \emptyset\).

An obvious but important property of the generic scheduler is given by the next lemma.

\textbf{Lemma 39:} If \(\alpha\) is a schedule of the generic scheduler then \(\alpha\) contains at most one return
event for each transaction T.

5.3. R/W Locking Systems

The composition of transactions with R/W Locking objects and the generic scheduler is called a *R/W Locking system*, and its operations and schedules are called *concurrent operations* and *concurrent schedules*, respectively.\(^\text{10}\) A sequence \(\alpha\) of concurrent operations is said to be *well-formed* provided that its projection at every transaction and R/W Locking object is well-formed. The following lemma is proved in the same way as Lemma 8.

**Lemma 40:** If \(\alpha\) is a concurrent schedule, then \(\alpha\) is well-formed.

The following lemma is straightforward.

**Lemma 41:** Let \(\alpha\) be a concurrent schedule. If T is a transaction that is not an orphan in \(\alpha\) and \(T'\) is visible to T in \(\alpha\), then \(T'\) is not an orphan in \(\alpha\).

Note that if \(\alpha\) is a concurrent schedule then any INFORM\_COMMIT\_AT(X)OF(T) is preceded by a COMMIT(T) event (by the scheduler preconditions) and similarly any INFORM\_ABORT\_AT(X)OF(T) is preceded by ABORT(T). Thus, if T is visible at X to \(T'\) in \(\alpha\) then T is visible to \(T'\) in \(\alpha\), and if T is an orphan at X in \(\alpha\) then T is an orphan in \(\alpha\). Thus, \(\text{visible}_X(\alpha, T)\) is a subsequence of \(\text{visible}(\alpha, T)|X\) when \(\alpha\) is a concurrent schedule.

Two important properties of R/W Locking systems are given next.

**Lemma 42:** Let \(\alpha = \alpha' \pi\) be a concurrent schedule where \(\pi\) is REQUEST\_CREATE(\(T'\)), COMMIT(\(T'\)) or ABORT(\(T'\)) for a child \(T'\) of T. Then \(\alpha'\) does not contain a COMMIT(T) event.

**Lemma 43:** Let \(\alpha\) be a concurrent schedule, T a transaction that is not an orphan in \(\alpha\) and M(X) a R/W Locking object. Then \(\text{visible}_X(\alpha, T)|X\) is a well-formed schedule of basic object X.

**Proof:** Let S denote the set of transactions with COMMIT events in \(\alpha\). Construct a sequence \(\beta\) by appending to \(\alpha\) a sequence of INFORM\_COMMIT\_AT(X)OF(U) events, where the U give a post-order traversal of S. Since \(\alpha\) contains a COMMIT(U) event for each U in S, \(\beta\) is a concurrent schedule, and by Lemma 37 \(\text{visible}_X(\beta, T)\) is a well-formed schedule of X. Since the INFORM\_COMMIT\_AT(X)OF(U) events at the end of \(\beta\) are in ascending order, and occur for every U that has committed to T in \(\beta\), \(\text{visible}_X(\beta, T) = \text{visible}(\beta, T)|X\). Also \(\text{visible}(\beta, T) = \text{visible}(\alpha, T)\) since INFORM\_COMMIT operations have no influence on what transactions are visible to T. Thus \(\text{visible}(\alpha, T)|X\) is a well-formed schedule of X. \(\square\)

---

\(^{10}\)Note that this usage differs from that in [LM].
6. The Proof of Serial Correctness

We prove that a R/W Locking system generates schedules that are serially correct for each non-orphan transaction T, by taking a concurrent schedule α, extracting the subsequence visible(α,T) of events whose effects might have been detected by T, and then rearranging the operations in this to give a serial schedule β. The rearrangements permitted are those that transform one sequence into a write-equivalent\(^{11}\) one.

6.1. Write-Equivalence

Two sequences of serial operations, γ and γ', are write-equivalent if
1. they contain the same events,
2. for each transaction U, γ|U = γ'|U, and
3. for each basic object X, γ|X and γ'|X are write-equal sequences of operations of X.

Thus, the rearrangements allowed include interchanging the order of two events of different transactions or objects, and also interchanging the order of events of a single object, provided that they are not both REQUEST_COMMITs for write accesses. By the semantic conditions of Section 4.3, such rearrangements at objects are such that the difference between the orders is not detectable by any later operations of that object. This property is expressed by the following lemma.

**Lemma 44:** If α and β are write-equivalent sequences, and α|X and β|X are well-formed schedules of X for each basic object X, then α|X and β|X are equieffective sequences.

When we use this lemma, α and β will each be either a serial schedule or the subsequence of a concurrent schedule visible to a transaction, and so the hypothesis that α|X and β|X are well-formed schedules of X will be satisfied for all basic objects X, by Lemmas 8 and 43.

Write-equivalence is obviously an equivalence relation. We have some straightforward results.

**Lemma 45:** If α and β are sequences of operations that are write-equivalent, then βϕ is write-equivalent to αϕ for any sequence ϕ of operations.

**Lemma 46:** If α and β are serial schedules that are write-equivalent and αϕ is a serial schedule then βϕ is a serial schedule.

**Proof:** From Lemma 45 we see that for any non-access transaction U, βϕ|U = αϕ|U which is a schedule of U, since αϕ is a serial schedule. For each basic object X, by Lemma 44 α|X is equieffective to β|X, so βϕ|X is equieffective to αϕ|X, and since αϕ|X is a schedule of X, so is βϕ|X. Thus, we need only show that βϕ is a schedule of the serial scheduler. For β this is a hypothesis of the lemma, and events in ϕ are enabled at the serial scheduler, because by Lemma 7 the preconditions of operations of the serial scheduler depend only on the presence or absence of operations in the preceding schedule, not on the order of those events. □

\(^{11}\)this notion is a generalization of equivalence as defined in [LM]
6.2. A Technical Lemma

In this subsection, we prove a result similar to Lemma 19, for use in the proof of Lemma 48 in Section 6.3.

**Lemma 47:** Let \( \alpha \) be a concurrent schedule, and let \( T \) and \( T' \) be two non-orphan transactions with \( T' \) visible to \( T \) in \( \alpha \). Let \( \beta \) and \( \beta_1 \) be serial schedules such that \( \beta \) is write-equivalent to \( \text{visible}(\alpha, T) \) and \( \beta_1 \) is write-equivalent to \( \text{visible}(\alpha, T') \). Then \( \gamma = \beta_1(\beta - \beta_1) \) is a serial schedule that is write-equivalent to \( \text{visible}(\alpha, T) \).

**Proof:** First we prove that \( \beta' = \text{visible}(\beta, T') \) is write-equivalent to \( \beta_1 \). By Lemma 15 and Lemma 13, \( \beta' \) and \( \beta_1 \) contain the same events. For any basic object \( X \), \( \text{write}(\beta'|X) = \text{write}(\beta_1|X) \) since \( \text{REQUEST\_COMMIT} \) events for write accesses to \( X \) occur in \( \beta' \) in the same order as they occur in \( \beta \), which is the same as the order they occur in \( \alpha \), which is the same as the order they occur in \( \beta_1 \). For any transaction \( U \) that is visible to \( T' \) in \( \alpha \) (and hence in \( \beta \)), \( \beta'|U = \beta|U = \alpha|U \), by Lemma 14 and write-equivalences, and similarly \( \beta_1|U = \alpha|U \). On the other hand, if \( U \) is not visible to \( T' \) in \( \alpha \), \( \beta'|U \) and \( \beta_1|U \) are both empty.

By Lemma 19, \( \beta'(\beta - \beta') \) is a serial schedule. Since \( \beta - \beta' = \beta - \beta_1 \) (as \( \beta' \) and \( \beta_1 \) contain the same events) and \( \beta' \) is write-equivalent to \( \beta_1 \), we deduce from Lemma 46 that \( \gamma \) is a serial schedule.

Next, we prove that \( \text{write}(\text{visible}(\alpha, T')|X) \) is a prefix of \( \text{write}(\text{visible}(\alpha, T)|X) \) for any object \( X \). Suppose that \( \text{visible}(\alpha, T) \) contains a \( \text{REQUEST\_COMMIT}(U, u) \) event for a write access \( U \) to \( X \) that is not in \( \text{visible}(\alpha, T') \). Let \( \text{REQUEST\_COMMIT}(U', u') \) be a subsequent event, where \( U' \) is a write access to \( X \) that is visible to \( T \) in \( \alpha \). We must show that \( U' \) is not visible to \( T' \) in \( \alpha \). Consider the prefix \( \delta \) of \( \alpha \) that precedes the \( \text{REQUEST\_COMMIT}(U', u') \), and let \( s \) denote the state of the R/W Locking object \( M(X) \) after \( \delta \). If we denote by \( U'' \) the highest ancestor of \( U \) to which \( U \) has committed in \( \alpha \), then \( U'' \) is a proper descendant of \( \text{lc}(U, T') \), since \( U \) is not visible to \( T' \) in \( \alpha \). Then the highest ancestor of \( U \) to which \( U \) is committed at \( X \) in \( \delta \) must be a descendant of \( U'' \), and so by Lemma 35 some descendant of \( U'' \) is in \( s\).write-locks holders. By the preconditions for the operation \( \text{REQUEST\_COMMIT}(U', u') \) of \( M(X) \), \( U' \) must be a descendant of \( U'' \), and therefore \( U' \) is not committed in \( \alpha \) to \( \text{lc}(U', T') = \text{lc}(U'', T') \). Therefore \( U' \) is not visible to \( T' \) in \( \alpha \), establishing that \( \text{write}(\text{visible}(\alpha, T')|X) \) is a prefix of \( \text{write}(\text{visible}(\alpha, T)|X) \).

Now we show that \( \gamma \) is write-equivalent to \( \beta \). They clearly contain the same events, since every event of \( \beta_1 \) occurs in \( \beta \) (because any operation visible to \( T' \) in \( \alpha \) is also visible to \( T \) in \( \alpha \) by Lemma 12). If \( P \) is a basic object, \( \text{write}(\beta_1|P) = \text{write}(\text{visible}(\alpha, T')|P) \) is a prefix of \( \text{write}(\text{visible}(\alpha, T)|P) = \text{write}(\beta|P) \), so that \( \text{write}(\gamma|P) = (\text{write}(\beta_1|P))(\text{write}(\beta|P) - \text{write}(\beta_1|P)) = \text{write}(\beta|P) \). If \( P \) is a transaction that is visible to \( T' \) in \( \alpha \) then \( \beta_1|P = \text{visible}(\alpha, T')|P = \alpha|P = \text{visible}(\alpha, T)|P = \beta|P \), so \( \gamma|P = (\beta_1|P)(\beta|P - \beta_1|P) = \beta|P \). On the other hand, if \( P \) is a transaction not visible to \( T' \) in \( \alpha \) then \( \beta_1|P \) is empty, so trivially \( \gamma|P = \beta|P \).

Since \( \gamma \) is write-equivalent to \( \beta \), it is write-equivalent to \( \text{visible}(\alpha, T) \). \( \square \)
6.3. The Main Results

We are now ready to prove that R/W Locking systems are serially correct for every transaction that is not an orphan. We actually state a stronger property that carries useful invariants through the induction.

**Lemma 48:** Let $\alpha$ be a concurrent schedule, and $T$ any transaction that is not an orphan in $\alpha$. Then there is a serial schedule $\beta$ that is write-equivalent to $\text{visible}(\alpha,T)$.

**Proof:** The proof follows the outlines of that of the main theorem of [LM]. We proceed by induction on the length of $\alpha$. As before, let $\alpha = \alpha' \pi$. We must show that there is a serial schedule $\beta$ that is write-equivalent to $\text{visible}(\alpha,T)$. We can assume that transaction $\pi$ is visible to $T$ in $\alpha$. There are seven cases, and in each we relate $\text{visible}(\alpha,T)$ to $\text{visible}(\alpha',U)$ for one or more transactions $U$, and build $\beta$ from serial schedules write-equivalent to $\text{visible}(\alpha',U)$.

1. $\pi$ is an output operation of a non-access transaction $T'$.

Since $T$ is not an orphan in $\alpha'$, the inductive hypothesis implies the existence of a serial schedule $\beta'$ that is write-equivalent to $\text{visible}(\alpha',T)$. Let $\beta = \beta' \pi$. We will show that $\beta$ is a serial schedule that is write-equivalent to $\text{visible}(\alpha,T)$. By Lemma 1, to check that $\beta$ is a serial schedule we need only check that $\beta' \pi | T'$ is a schedule of $T'$. However $\beta' | T' = \text{visible}(\alpha',T) | T' = \alpha' | T'$ by Lemma 14 (since $T'$ is visible to $T$). Thus $\beta' \pi | T' = \alpha' | T' = \alpha | T'$, which is a schedule of $T'$. Thus, $\beta$ is a serial schedule.

By Lemma 16, $\text{visible}(\alpha,T) = \text{visible}(\alpha',T) \pi$ and since $\beta'$ is write-equivalent to $\text{visible}(\alpha',T)$, we may apply Lemma 45 to deduce that $\beta$ is write-equivalent to $\text{visible}(\alpha,T)$.

2. $\pi$ is an output operation of a R/W Locking object $M(X)$.

Since $T$ is not an orphan in $\alpha'$, the inductive hypothesis implies the existence of a serial schedule $\beta'$ that is write-equivalent to $\text{visible}(\alpha',T)$. Let $\beta = \beta' \pi$. We will show that $\beta$ is a serial schedule that is write-equivalent to $\text{visible}(\alpha,T)$. By Lemma 1, to check that $\beta$ is a serial schedule we need only check that $\beta' \pi | X$ is a schedule of $X$. However, Lemma 44 implies that $\beta' | X$ is equieffective to and contains the same events as $\text{visible}(\alpha',T) | X$. Now $\text{visible}(\alpha',T) \pi | X = \text{visible}(\alpha',T) | X = \text{visible}(\alpha,T) | X$, which is a schedule of $X$ by Lemma 43. Thus by Lemma 24, $\beta' \pi | X$ is a schedule of $X$. Thus $\beta$ is a serial schedule.

Since $\text{visible}(\alpha,T) = \text{visible}(\alpha',T) \pi$, $\beta = \beta' \pi$, and $\beta'$ is write-equivalent to $\text{visible}(\alpha',T)$, we may apply Lemma 45 to deduce that $\beta$ is write-equivalent to $\text{visible}(\alpha,T)$.

3. $\pi$ is a CREATE($T'$) operation.

Then transaction $\pi = T'$, and so $T'$ is visible to $T$ in $\alpha$. By well-formedness and the scheduler preconditions, any operation of a proper descendant of $T'$ must be preceded by a REQUEST_CREATE for a child of $T'$, and by well-formedness any operation of $T'$ must follow CREATE($T'$). Thus, $\pi$ is the first event whose transaction is a descendant of $T'$, so $T' = T$. By Lemma 21, parent($T$) is not an orphan in $\alpha$, and hence in $\alpha'$, so the inductive hypothesis implies the existence of a serial schedule $\beta'$ that is write-equivalent to $\text{visible}(\alpha',\text{parent}(T))$. Let $\beta = \beta' \pi$. We will show that $\beta$ is a serial schedule that is write-equivalent to $\text{visible}(\alpha,T)$.

To show that $\beta$ is a serial schedule, we need only check that $\beta' \pi$ is a schedule of the serial scheduler. If $s'$ is the state of the serial scheduler after an execution with operation sequence $\beta'$, we will show that $\pi$ is enabled in $s'$. We note that $\pi$ was enabled in the state $s''$ of the generic scheduler that arose from the execution with operation sequence $\alpha'$. Thus from the
preconditions for $\pi$ in the generic scheduler and from Lemma 38 we see that $\alpha'$ must contain REQUEST_CREATE(T) but not CREATE(T), and since T is not an orphan in $\alpha$, no ABORT(T) event occurs in $\alpha'$. These conclusions also hold for visible($\alpha'$,parent(T)) since REQUEST_CREATE(T) occurs at parent(T) and any operation absent in $\alpha'$ must be absent from its subsequence visible($\alpha'$,parent(T)). Since $\beta'$ is write-equivalent to visible($\alpha'$,parent(T)) it contains the same events, and so $\beta'$ contains REQUEST_CREATE(T) but no CREATE(T) or ABORT(T) event, and Lemma 7 shows that T $\in$ s'.create-requested - (s'.created $\cup$ s'.aborted). Also for any U $\in$ sibling(T), if U $\in$ s'.created then CREATE(U) occurs in $\beta'$ and hence in visible($\alpha'$,parent(T)), so U must be visible to parent(T) in $\alpha'$, so COMMIT(U) must occur in $\alpha'$ and thus in visible($\alpha'$,parent(T)) (as it has transaction parent(U) $=$ parent(T)), and so COMMIT(U) occurs in $\beta'$. By Lemma 7, U $\in$ s'.returned, establishing that sibling(T) $\cap$ s'.created $\subseteq$ s'.returned. Thus we have checked that $\pi$ is enabled in s', and therefore $\beta = \beta'\pi$ is a serial schedule.

Since visible($\alpha$,T) = visible($\alpha'$,parent(T))$\pi$, $\beta = \beta'\pi$ and $\beta'$ is write-equivalent to visible($\alpha'$,parent(T)), we may deduce from Lemma 45 that $\beta$ is write-equivalent to visible($\alpha$,T).

(4) $\pi$ is a COMMIT(T') operation.

Then T" = parent(T') is visible to T in $\alpha$, since transaction($\pi$) = T". Lemma 42 says that no COMMIT(T") occurs in $\alpha'$, and so T must be a descendant of T" (since T" is visible to T). Also, by Lemma 41, T" is not an orphan in $\alpha$ and so T" is not an orphan in $\alpha'$. From this and Lemma 39, we deduce that T' is not an orphan in $\alpha'$. We distinguish two cases, depending on whether T is a descendant of T' or not.

Assume first that T is a descendant of T'. Then visible($\alpha$,T) = visible($\alpha'$,T)$\pi$, and by the induction hypothesis there is a $\beta'$ that is serial and write-equivalent to visible($\alpha'$,T). Let $\beta = \beta'\pi$. We show that $\beta$ is a serial schedule that is write-equivalent to visible($\alpha$,T). To show that $\beta$ is serial, we must show that $\pi$ is enabled at the serial scheduler after $\beta'$. The serial scheduler preconditions and Lemma 7 show that we must prove that REQUEST_COMMIT(T',v) occurs in $\beta'$, that no return for T' occurs in $\beta'$, and that for every child U of T' with a REQUEST_CREATE(U) in $\beta'$ there is a return event in $\beta'$. Since $\pi$ is enabled in the generic scheduler after $\alpha'$, each of these is true with $\alpha'$ replacing $\beta'$. Since all these operations are visible to T in $\alpha'$, all these statements are also true of visible($\alpha'$,T) and thus of the write-equivalent sequence $\beta'$, as required. Now we note that Lemma 45 proves that $\beta = \beta'\pi$ is write-equivalent to visible($\alpha$,T) = visible($\alpha'$,T)$\pi$.

In the other case, when T is not a descendant of T', the inductive hypothesis yields three serial schedules, $\beta'$, $\beta''$ and $\gamma$, that are write-equivalent to visible($\alpha'$,T'), visible($\alpha'$,T) and visible($\alpha'$,T'') respectively. Let $\beta_1 = \beta'$ - $\gamma$ and $\beta_2 = \beta'' - \gamma$. Let $\beta = \gamma\beta_1\pi\beta_2$. We show that $\beta$ is a serial schedule that is write-equivalent to visible($\alpha$,T). That $\beta$ is serial follows from Lemma 27, provided we can show that:

(4.a) $\gamma\beta_1\pi$ is a serial schedule,
(4.b) $\gamma\beta_2$ is a serial schedule,
(4.c) $\gamma\beta_1 = \text{visible}(\gamma\beta_1,T')$,
(4.d) $\gamma\beta_2 = \text{visible}(\gamma\beta_2,T)$,
(4.e) $\gamma = \text{visible}(\gamma\beta_1,T'') = \text{visible}(\gamma\beta_2,T''')$ and $\gamma$ is visible,
(4.f) if any basic object X has an output operation in $\beta_2$ then every operation in $\beta_1 | X$ is transparent.

(4.a) By Lemma 47, $\gamma\beta_1$ is a serial schedule (and is write-equivalent to visible($\alpha'$,T')). We must therefore show that $\pi$ is enabled at the serial scheduler after $\gamma\beta_1$. The serial scheduler
preconditions and Lemma 7 show that we must prove that REQUEST_COMMIT(T',v) occurs in \( \gamma_1 \) for some \( v \), that no return for T’ occurs in \( \gamma_1 \), and that for every child U of T’ with a REQUEST_CREATE(U) in \( \gamma_1 \) there is a return event in \( \gamma_1 \). Since \( \pi \) is enabled in the generic scheduler after \( \alpha' \), each of these is true with \( \alpha' \) replacing \( \gamma_1 \). Since all these operations are visible to T’ in \( \alpha' \), all these statements are also true of \( \text{visible}(\alpha', T') \) and thus of the write-equivalent sequence \( \gamma_1 \), as required. Thus \( \gamma_1 \pi \) is a serial schedule. We also note that Lemma 45 proves that \( \gamma_1 \pi \) is write-equivalent to \( \text{visible}(\alpha', T') = \text{visible}(\alpha', T') \pi \).

(4.b) By Lemma 47, \( \gamma_2 \) is serial (and write-equivalent to \( \text{visible}(\alpha', T) \)).

Parts (4.c)-(4.e) are immediate.

(4.f) We prove that if a basic object X has an output operation in \( \beta_2 \), then no event in \( \beta_2 \) is a REQUEST_COMMIT for a write access. Suppose this were false. Then \( \beta_2 \) contains a REQUEST_COMMIT(V_1,v_1) for \( V_1 \) a write access to X, and \( \beta_2 \) contains a REQUEST_COMMIT(V_2,v_2) for \( V_2 \) an access to X. Since \( V_1 \) is visible in \( \alpha \) to T’ but not to T’’, \( V_1 \) must be a descendant of T’, and not an orphan in \( \alpha \), and \( V_1 \) must not be committed at X to T’’ in \( \alpha \). By Lemma 35, some descendant of T’ is in s.write-lockholders, where s is a state of M(X) after applying \( \alpha \). Similarly \( V_2 \) must be a descendant of some sibling U of T’ but not committed at X to T’’ in \( \alpha \), so by Lemma 35, some descendant of U is in s.read-lockholders \( \cup \) s.write-lockholders. But these two statements about lockholders contradict Lemma 34.

Now we must prove that \( \beta \) is write-equivalent to \( \text{visible}(\alpha, T) \). Since any transaction visible to T in \( \alpha \) is either visible to T in \( \alpha' \) or visible to T’ in \( \alpha' \) and if both then it is visible to T” in \( \alpha' \), it is clear that \( \beta \) and \( \text{visible}(\alpha, T) \) contain the same events. If \( P \) is a basic object, either \( \beta_2 \) contains no output operations of \( P \) or else no operation in \( \beta_1 \) is a REQUEST_COMMIT for a write access. In the first case \( \text{write}(\beta_2 \pi \mid P) \) is empty, and since \( \text{write}(\gamma_1 \pi \mid P) = \text{write}(\text{visible}(\alpha', T') \mid P) \), we have \( \text{write}(\beta_2 \mid P) = \text{write}(\text{visible}(\alpha, T) \mid P) \). In the second case \( \text{write}(\beta_1 \mid P) \) is empty, and since \( \text{write}(\gamma_2 \mid P) = \text{write}(\text{visible}(\alpha', T') \mid P) \), we again have \( \text{write}(\beta_1 \mid P) = \text{write}(\text{visible}(\alpha, T) \mid P) \). If \( P \) is a non-access transaction that is not visible to T in \( \alpha \), then no operations occur at \( P \) in either \( \beta \) or \( \text{visible}(\alpha, T) \). For \( P \) any non-access transaction that is visible to T in \( \alpha \), either P is visible to T in \( \alpha' \) or \( P \) is visible to T’ in \( \alpha' \). In the first case, \( \beta_2 \mid P \) is empty so \( \beta_2 \mid P = \gamma_1 \pi \mid P = \text{visible}(\alpha, T') \mid P \) since we saw above that \( \gamma_1 \pi \) and \( \text{visible}(\alpha, T') \) are write-equivalent, and \( \text{visible}(\alpha, T') \mid P = \alpha \mid P \mid \text{visible}(\alpha, T) \mid P \). Similarly in the second case \( \beta_1 \pi \mid P \) is empty and \( \beta_1 \pi \mid P = \gamma_2 \pi \mid P = \text{visible}(\alpha, T') \mid P \mid \text{visible}(\alpha, T) \mid P \). In every case, we have checked that \( \beta \mid P = \text{visible}(\alpha, T) \mid P \). Thus \( \beta \) and \( \text{visible}(\alpha, T) \) are write-equivalent.

(5) \( \pi \) is an ABORT(T’) operation. Then T” = parent(T’) is visible to T in \( \alpha \), since transaction(\( \pi \)) = T”’. Lemma 42 says that COMMIT(T”’) does not occur in \( \alpha' \) and so T must be a descendant of T”’ (since T”’ is visible to T). Also by Lemma 41, T”’ is not an orphan in \( \alpha \) and so also T”’ is not an orphan in \( \alpha' \). Since T is not an orphan in \( \alpha, T \) is not a descendant of T’. Thus the inductive hypothesis yields two serial schedules, \( \beta' \) and \( \gamma \), that are write-equivalent to \( \text{visible}(\alpha', T') \) and \( \text{visible}(\alpha', T'') \) respectively. Let \( \beta_1 = \beta' - \gamma \). Let \( \beta = \gamma \beta_1 \). We show that \( \beta \) is a serial schedule that is write-equivalent to \( \text{visible}(\alpha, T) \). That \( \beta \) is serial follows from Lemma 28, provided we can show that:

(5a) \( \gamma \pi \) is a serial schedule,
(5b) \( \gamma \beta_1 \) is a serial schedule,
(5.c) $\gamma \beta_1 = \text{visible}(\gamma \beta_1, T)$,
(5.d) $\gamma = \text{visible}(\gamma, T'') = \text{visible}(\gamma \beta_1, T'').$

(5.a) Since $\gamma$ is a serial schedule, we must show that $\pi$ is enabled at the serial scheduler after $\gamma$. The serial scheduler preconditions and Lemma 7 show that we must prove that REQUEST _CREATE($T'$) occurs in $\gamma$, and that no CREATE($T'$) or ABORT($T'$) occurs in $\gamma$. Since $\pi$ is enabled in the generic scheduler after $\alpha'$, $\alpha'$ contains a REQUEST _CREATE($T'$) event, and since transaction(REQUEST _CREATE($T'$)) = $T''$, REQUEST _CREATE($T'$) is in $\text{visible}(\alpha', T'')$ and hence in $\gamma$. By Lemma 39, $T'$ is not committed in $\alpha'$, so that any CREATE($T'$) event in $\alpha'$ is not visible to $T''$, and so does not occur in $\text{visible}(\alpha', T'')$ and hence does not occur in $\gamma$. By Lemma 39, there is no ABORT($T'$) event in $\alpha'$, so ABORT($T'$) does not occur in $\gamma$. Thus $\gamma \pi$ is a serial schedule. We also note that Lemma 45 proves that $\gamma \pi$ is write-equivalent to $\text{visible}(\alpha, T') = \text{visible}(\alpha', T') \pi$, since $\gamma$ and $\text{visible}(\alpha', T')$ are write-equivalent.

(5.b) By Lemma 47, $\gamma \beta_1$ is a serial schedule (and it is write-equivalent to $\text{visible}(\alpha', T)$).

Parts (5.c) and (5.d) are immediate.

Now we must prove that $\beta$ is write-equivalent to $\text{visible}(\alpha, T)$. Since any transaction visible to $T$ in $\alpha$ is visible to $T$ in $\alpha'$, and either visible to $T''$ in $\alpha'$ or not, it is clear that $\beta$ and $\text{visible}(\alpha, T)$ contain the same events. If $P$ is a basic object, since $\text{write}(\gamma \beta_1|P) = \text{write}(\text{visible}(\alpha', T')|P)$ we have $\text{write}(\beta|P) = \text{write}(\text{visible}(\alpha, T)|P)$. For $P$ any non-access transaction, $\beta|P = \gamma \beta_1|P = \text{visible}(\alpha', T')|P = \text{visible}(\alpha, T)|P$, since $\pi|P$ is empty and $\gamma \beta_1$ and $\text{visible}(\alpha', T')$ are write-equivalent. This completes the demonstration that $\beta$ and $\text{visible}(\alpha, T)$ are write-equivalent.

(6) $\pi$ is REPORT _COMMIT($T', \nu$)
Since $T$ is not an orphan in $\alpha'$ there is a serial schedule $\beta'$ that is write-equivalent to $\text{visible}(\alpha', T)$. Put $\beta = \beta' \pi$. By the preconditions of the generic scheduler and Lemma 38, REQUEST _COMMIT($T', \nu$) and COMMIT($T'$) occur in $\alpha'$. Since the report is in $\text{visible}(\alpha', T)$, parent($T'$) is visible to $T$ in $\alpha'$; thus, COMMIT($T'$), and hence REQUEST _COMMIT($T', \nu$), are in $\text{visible}(\alpha', T)$. So COMMIT($T'$) and REQUEST _COMMIT($T', \nu$) occur in $\beta'$. The serial scheduler preconditions and Lemma 7 imply that $\pi$ is enabled after $\beta'$ at the serial scheduler, and so by Lemma 1 and Lemma 45, $\beta$ is a serial schedule that is write-equivalent to $\text{visible}(\alpha, T) = \text{visible}(\alpha', T) \pi$.

(7) $\pi$ is REPORT _ABORT($T'$)
This is just like case (6).

Thus in every case we have produced a serial schedule $\beta$ that is write-equivalent to $\text{visible}(\alpha, T)$. □

Theorem 49: Every concurrent schedule is serially correct for every non-orphan non-access transaction.

Proof: Let $T$ be a transaction that is not an orphan in the concurrent schedule $\alpha$. By Lemma 48 there is a serial schedule $\beta$ that is write-equivalent to $\text{visible}(\alpha, T)$. Then $\alpha|T = \text{visible}(\alpha, T)|T$ by Lemma 14, and by write-equivalence, $\text{visible}(\alpha, T)|T = \beta|T$. □

In particular, the external environment, modelled by $T_0$, receives responses from transactions that are consistent with a serial execution.
Corollary 50: Every concurrent schedule is serially correct for \( T_0 \).

7. Conclusions and Further Work

We have used I/O automata to provide clear formal descriptions of all the components of a nested transaction system that uses Moss’s algorithm to manage data. We have shown how to take any schedule of such a system, extract a subsequence (including all the operations of a given non-orphan transaction), and rearrange the events in the subsequence to give a write-equivalent serial schedule. Thus we have demonstrated that any schedule of a R/W locking system is serially correct for every non-orphan transaction.

This work by no means exhausts the topic of concurrency control and recovery in nested transaction systems. Work is currently underway on a number of issues orthogonal to the locking techniques considered in this paper, for example replication [GL] and orphan elimination [HLMW]. We also hope to extend the results of this paper in several ways. One natural extension is to locking protocols for abstract data types that allow more concurrency than R/W locking by using more semantic information about the operations. Such protocols have been studied in transaction systems without nesting [We]. In generalizing these protocols to handle nested transactions, it appears that equieffectiveness can be used to provide a natural definition of commutativity (or non-conflict) between operations, which can then be used to prove the correctness of an algorithm that generalizes conflict-based locking to nested systems.

Other aspects of real systems that we have not addressed in this paper, but expect to study in the future, are liveness properties and resilience to system crashes. We have proved that any response to a R/W locking system is correct, but for a practical system we also need to know that a response will be produced (and, we hope, rapidly produced.) Lynch and Tuttle [LT] discuss how to express liveness results in terms of I/O automata, but phenomena such as deadlock in transaction systems make it difficult to guarantee strong liveness properties. At best, any guarantees that progress can be made will be probabilistic. System crashes that cause information to be lost (such as lock tables) are also a reality of practical systems. We plan to extend the model presented in this paper to describe crashes, and to analyze algorithms that ensure resilience to crashes.
