Abstract

This thesis describes a suite of tools that were used to build an internet gateway, with powerful 3D and 2D visualizations and intuitive, directed navigation, to an expansive collection of geospatial imagery on the world-wide-web. The two driving visions behind this project were: 1) to develop a system for automatically providing flexible, modular and customizable infrastructure for navigating a hierarchical dataset based on a simple and concise description of the paths users can take to reach items in the dataset and 2) to create a visually exciting, interactive medium for members of the machine vision community to explore the data in the City Scanning Project Dataset and learn more about techniques the City Scanning Group is developing for rapidly acquiring geospatial imagery with very high precision. In an effort to realize these goals I have developed the DataLink Server, a system that provides navigation and data retrieval infrastructure for a dataset based on a specification written in a descriptive and coherent XML-based web navigation and data modeling language; a geospatial coordinate transformation library for converting coordinates in virtually any geographic or cartographic coordinate system; and a battery of visualization applications for exploring the epipolar geometry, baselines, vanishing points, edge and point features and position and orientation information of a collection of geospatial imagery. These tools have been successfully used to deploy a web interface to the more than 11,000 geospatial images that make up the City Scanning Project Dataset collected by the MIT Computer Graphics Group.

Thesis Supervisor: Seth Teller

Title: Associate Professor of Computer Science and Engineering

Acknowledgments

Patience is the cardinal virtue of any good teacher, and, therefore, I would first like to acknowledge my thesis advisor, Prof. Seth Teller, who, despite the impressive number of students, projects and courses he supervises, still finds time to sit down with any one of his students to share pointers about such humble subjects as debugging with gdb and working with a UNIX shell as eagerly as he provides insights on graphics algorithms, mathematics and other “hard-core” topics of computer science. I must also thank Mom for her unfaltering support and encouragement, Sis for her ever consummate advice, my brother Eric for restraining himself from dissuading me from coming to MIT and Dad, to whom I owe my love of the outdoors and my respect for the natural world. I should thank Prof. Patrick Henry Winston for reinvigorating in me a passion for real science and Professors Alan Lightman, Anita Desai and David Thorburn for all the distractions in fiction, literature and film.

In addition, thanks to everybody in the City group, Neel, Manish, Matt and Mike, for helping out along the way. Of all the groups in LCS, the City Scanning Group is the one with the most helpful, enthusiastic and cool people to work with.

Although I’ve never met him, Douglas Adams deserves recognition for impressing upon me the subtle wisdom of cynicism at a very young age (which was further cultivated by Kurt Vonnegut and Mark Twain, among others), and special thanks is due to The Clash and Rancid for creating the quality punk rock albums that provided much of the acoustical accompaniment to this work. On that note, while making a conscious effort not to make this read too much like the liner notes of a CD, I’d like to briefly mention: The Talking Heads, Nirvana, The Cure, The Spin Doctors, Counting Crows, Train, Brahms, Mozart, Beethoven, Gershwin, Copland, Isabelle Allende, Gabriel Garcia Marquez, Jim and William Reid, Jake Burton and the seminal noise acoustics band Sonic Youth.

And now for the real funky stuff...

Chapter 1

Introduction and Background Information

1.1 Background Information

The goal of the City Scanning Project is to develop an end-to-end system for automatically acquiring 3D CAD models of urban environments under uncontrolled lighting conditions (i.e. outside, under natural light) [Teller et al., 2001]. To achieve this goal the City Group has constructed a sensor for automatically acquiring pose-augmented imagery (image data coupled with position and orientation estimates) and a suite of post-processing algorithms to refine the position estimates and extract intrinsic parameters about building features. Using these tools the City Group has collected over 500 sets of pose-augmented images which make up we believe to be the largest dataset of geospatial imagery in existence.

The author had previously developed a world-wide-web based interface that allows people from anywhere in the world to browse is dataset. This web interface included a set of visualization tools that allow viewers to examine the quality of the data in various post-processing stages and learn more about the process by which the data is acquired [Bodnar, 2001]. This thesis outlines extensions and additions to the pre-existing web interface in order to make it a powerful tool for analyzing the data. These extensions make the web interface an easy-to-use exploration tool for members of the

general public to browse the data and learn more about the project, as well as a useful tool for members of the City Group to validate the data, evaluate the performance of the various processing stages and diagnose problems with the acquisition process.

This section outlines briefly what the reader needs to know about the image acquisition process and the pre-existing web interface. For more information about the data, or the image acquisition and post-processing stages please refer to *Calibrated, Registered Images of an Extended Urban Area* [Teller et al., 2001]. The previous version of the web interface is documented in *A Web Interface for a Large Calibrated Image Dataset* [Bodnar, 2001].

1.1.1 Image Acquisition and Post-processing Stages

Pose images are collected using a robotic sensor which consists primarily of a digital camera mounted on pan-tilt head [De Couto, 1998]. The sensor is equipped with an on-board GPS receiver, inertial motion sensors, a compass and wheel odometers which are used to obtain reasonably accurate position and orientation estimates for each of the images [Bosse et al., 2000]. When the sensor is activated at a given location, the camera head rotates about a fixed optical center capturing between 20 and 71 images tiling a portion of the sphere. One such collection of images, in combination with the associated position and orientation information, is referred to as a *node*.

The images for each node are numbered sequentially beginning at zero. The position and orientation data for each image is logged in a camera file with an ID number matching that of the associated image.¹ The camera files generated by the sensor are what is referred to as the *initial* pose data.

When the sensor has been returned to the lab and the new nodes have been added to the City database, an edge and point feature detection algorithm is applied to the images. Then the initial pose files are subjected to a series of post-processing algorithms to refine the position and orientation estimates. All of these algorithms are applied in a sequence of four post-processing stages: feature detection, mosaicing, ro-

¹For more information about the format of a camera file and its contents, please refer to *Calibrated, Registered Images of an Extended Urban Area* [Teller et al., 2001].

tational alignment and translational registration/geo-referencing. Each of these stages outputs a new set of camera files. The camera files from previous stages are kept in a directory named after the post-processing stage that generated them. Each stage can be described briefly as follows:

Feature Detection

During this stage edge and point features are extracted from each of the raw images for use in later post-processing stages. This stage outputs edge and point feature files.

Mosaic

At this stage the overlapping regions of the raw images are aligned. The images are then blended together and resampled to form a spherical texture. The camera files generated by this stage for a given node have improved orientation estimates relative to each other. This stage outputs spherical textures and mosaiced camera files.²

Rotation

Edge features are used in the rotation phase to detect vanishing points (points where families of parallel lines seem to converge when viewed from the optical center of the node). The rotation process relies on the assumption that nearby nodes will share some common vanishing points because they view some of the same building façades. The nodes are rotated in an attempt to align the shared vanishing points of adjacent nodes. The result is further refinement of the orientation estimates. This stage outputs vanishing points, node adjacencies³ and rotated camera files.⁴

²Please see *Spherical Mosaics with Quaternions and Dense Correlation*, [Coorg and Teller, 2000] for more information about the algorithms used in the mosaic stage.

³A node is adjacent to any of its 3 (or sometimes 4) nearest neighbors and any other nodes within a certain radius. Adjacencies are used to determine which nodes are likely to share common features, such as vanishing points.

⁴See *Automatic Recovery of Relative Camera Rotations for Urban Scenes* [Antone and Teller, 2000] for more information about the rotation stage.

Translation and Georeferencing

As a node is moved in a straight line, points on the spherical texture seem to emerge from a common point as they move toward the viewer and converge at an antipodal point as they move away from the viewer. These two points define a baseline. By attempting to align baselines directions with the directions between two nearby nodes, the translation process refines the relative position estimates of the nodes. Then GPS estimates from the sensor are then used to scale, translate, and rotate the camera positions to obtain new estimates that best fit the surveying data. This stage outputs baselines for each pair of adjacent nodes and camera files with revised position estimates.⁵

1.1.2 Description of the Existing Interface

The existing web interface consists of a number of HTML documents, CGI scripts and Java applets which allow the user to browse the nodes, view the camera files and feature files as well as view thumbnails of the raw images. It also includes a number of visualization tools which allow the user to view the spherical textures, adjacencies, epipolar geometry, node locations as well as many other features of the data. Finally, it provides a remapping of the physical data structure of the dataset to a simpler logical hierarchy more suitable for web-browsing.

The Pre-existing Visualization Tools

At the core of the pre-existing web interface are the visualization applets. This section describes the functionality of each of these applets briefly.

The Map Viewer The Map Viewer shows the positions of the nodes superimposed upon a map of campus. The node locations are shown in different colors corresponding to their level of post-processing refinement. The Map Viewer can zoom in to show a

⁵See *Scaleable, Absolute Position Recovery for Omni-Directional Image Networks* [Antone and Teller, 2001] for more information about the translation/georeferencing stage.

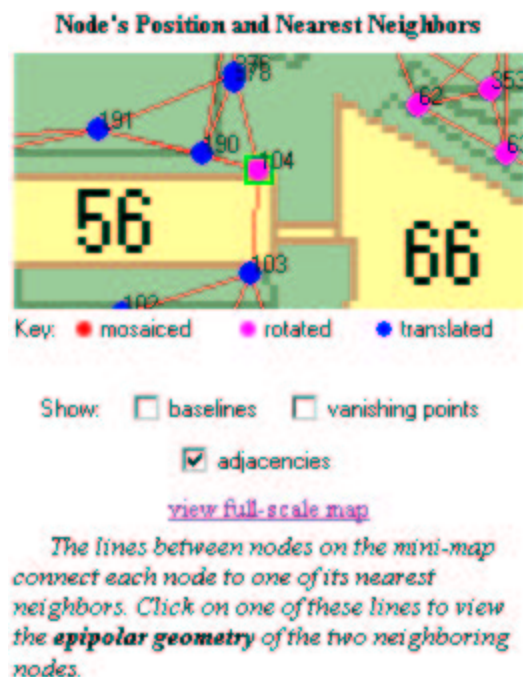

Figure 1-1: A screen-shot of the Map Viewer zoomed in to show node 104

close up view of a region of campus and can display adjacencies as lines which connect node locations. Clicking on a node location redirects the user to a CGI generated HTML document that displays information about the node, including images, links to the pose and feature data as well as some other visualization tools. Clicking on an edge between two nodes brings up the Epipolar Viewer (see below) for the implicated node pair. Figure 1-1 is a screen-shot of the Map Viewer in mini-mode.

The Mosaic Viewer This tool allows the user to view the spherical texture from the point of view of the optical center of the node, looking out. Using the mouse or the keyboard the vantage point can be rotated vertically or horizontally and the field of view can be zoomed in or out. The Mosaic Viewer in the pre-existing interface is equipped with a gamma correction tool which compensates for the sometimes strange coloration of the images (due to the fact that the images have a high dynamic range logarithmically mapped onto a linear scale from 0-255) by boosting the color saturation of the image.

Images in the city dataset are encoded using the SGI .rgb file format [Haeberli, 2002].

The .rgb format is not very web-friendly; it is neither supported by most web-browsers nor the standard Java API. To ameliorate this problem, the existing toolkit used to rely on a script that was run prior to the deployment of the web interface, which generates .jpg encoded versions of the spherical textures. One of the extensions to the pre-existing web interface was to augment the Mosaic Viewer (and the other applets that use .rgb images) with a Java utility class, `RGBImage`, that can decode radiance encoded .rgb images. This both eliminates the need to generate .jpg versions of the images for web-viewing and the problems with color saturation (see Section 7.1.4 for more information about the `RGBImage` class). Figure 1-2 is a screen-shot of the Mosaic Viewer displaying some of the enhancements described in this thesis (see Section 7.1).

The Epipolar Viewer The Epipolar Viewer is a two panel version of the Mosaic Viewer. Each panel shows the view from one node of a pair of adjacent nodes. In each view the neighboring node is marked by a blue cross. The Epipolar Viewer allows the user to project a ray from the center of one view and see the corresponding line as viewed from the neighboring node. For a pair of perfectly aligned nodes the ray should appear to intersect the same points in space in both views, thus allowing the user to visually inspect the quality of the position and orientation estimates generated by the post-processing routines. The user can select, using a drop down menu, which set of pose data to use when rendering the epipolar lines. This allows the user to observe how the position and orientation estimates improve with each post-processing stage. Figure 1-3 shows a screen shot of the Epipolar Viewer being used to examine two views of *The Great Sail*.⁶ In Figure 1-3 the Epipolar Viewer has been augmented with some of the advanced features described in this thesis (see Section 7.1).

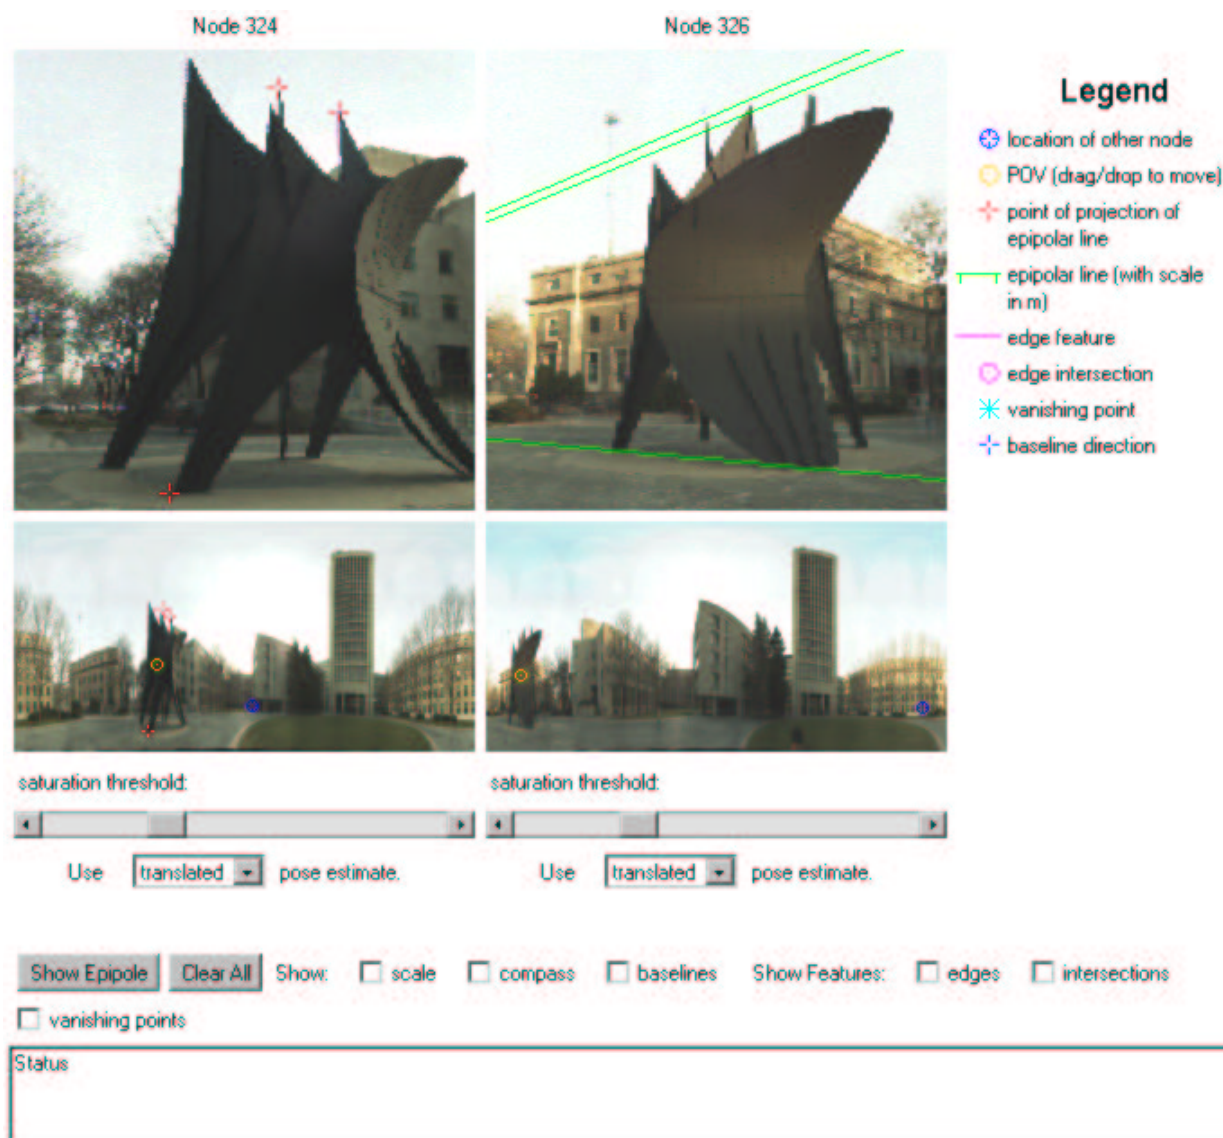

Figure 1-3: A screen-shot of the Epipolar Viewer comparing the geometry of two views of *The Great Sail*

1.2 Overview of the Extended Interface

The extended interface has roughly the same look and feel as the original pre-existing interface. It allows users to browse the dataset in nearly the same fashion as before and view the data using improved versions of the visualization applets described in the previous section. In addition to enhanced functionality, the new web interface is backed by a new, powerful and versatile navigation infrastructure whose core is a Java servlet package called the *DataLink Server*. A C++ static library for transforming Earth coordinates has also been added to the visualization toolkit allowing the dataset to be used in conjunction with data from outside sources expressed in almost any geographic, geocentric, or cartographic coordinate system. This section gives a brief overview of the DataLink Server, the coordinate transformation library and other minor extensions and improvements that have been made to the pre-existing interface, all of which will be described in greater detail in subsequent chapters.

1.2.1 The DataLink Server

For the pre-existing web interface, the abstraction between the organization of the data presented to the user and its arrangement on the physical disk is provided by a few Perl scripts. These scripts traverse the directory tree of the physical data and generate symbolic links to the relevant files. They must be run prior to deployment of the web site. The symbolic link trees re-map the complicated directory structure of the physical data to a simpler hierarchy that is more suitable for browsing on the web [Bodnar, 2001]. Although re-mapping the data in this way effectively provides the desired abstraction, the symbolic links are problematic in that they must be regenerated every time there are additions to the data.⁷ In addition, any changes in

⁷One might consider running these scripts in a crawler-like mode to automatically incorporate additions and deletions. However, this involves both the creation and removal of symbolic links in the public HTML directory of the web interface so it is likely to cause irritating 404 - Not Found messages and other disruptions if the dataset is modified at the same time it is being browsed by a user, due to the caching that is performed by most web browsers. Also, the DataLink Server is capable of incorporating updates in real time, whereas the crawler scripts would have to be run episodically.

the organization of the physical data or its layout on the web requires modification of the Perl scripts themselves which necessitates, at a minimum, decent working knowledge of the dataset, the operation of the scripts and the Perl programming language.

The DataLink Server provides a more versatile solution to this problem. The Data Link Server is a web application consisting of Java servlets and Java Server Pages (JSPs) that provide an abstraction function between a particular web layout and a physical data store. The DataLink Server allows a web designer to define one or more alternative *logical* arrangements of the data using a simple XML-based modeling language. The hierarchical organization of these logical arrangements may be completely different from the layout of the physical data. Using the XML description of the web layout and a similar XML-based model of the physical data, the DataLink Server automatically resolves the mapping between the logical hierarchy of the presentation layer and the location of the physical data on they fly as the information is browsed by a user. In addition, the DataLink Server allows the web architect to specify *content managers*, which are additional JSPs or servlets that generate the HTML for presenting a particular datum, giving the web designer complete control over the look and feel of the front end.

This infrastructure provides a number of key benefits over the pre-existing script-generated architecture:

- As new data is added to the dataset it becomes instantly available for browsing via the web interface because the mapping between the web layout and the physical layout is resolved at run time.
- No broken links result from the renaming or removal of data because the DataLink Server will only resolve mappings to existing physical data.
- Information about the layout of the presentation layer is centralized in a single XML document, so reorganizing the entire web site can be done by editing a single file.

- The description of the physical data hierarchy is described in a solitary XML file as well, so restructuring of the physical data hierarchy only necessitates modifications to one document in order to update the web interface.
- The DataLink server allows the web architect to describe multiple logical hierarchies of the data, any of which may be navigated by the user to arrive at the same data.
- Content Managers make it possible to create a *modular* customized façade for the front end of the interface.
- The DataLink Server handles updates in real time.

In addition to these advantages, the DataLink Server also improves the efficiency of the web interface by employing a caching strategy for large blocks of commonly accessed data (such as the locations of the nodes to be plotted by the Map Viewer) and performs user auditing to help the City group keep tabs on the site's usage. The complete details about the caching strategy and user auditing, as well as the inner workings of the DataLink Server itself and the XML-based modeling language are discussed in Chapters 2-4.

1.2.2 The Geospatial Coordinate Transformation Library

The City Scanning Project dataset uses a local tangent plane (LTP) coordinate system for all of its position and orientation data. This coordinate system is defined by a right handed set of axes with the x axis pointing east, the y axis pointing north and the z axis pointing up (normal to the Earth) with units in meters.⁸ The origin is located at the position of the GPS base station antenna (on the roof of building NE43 in Tech Square) that the City group uses to obtain differential GPS measurements of the nodes' placement. This coordinate system is used to provide the highest degree of precision to position estimates acquired using differential GPS. The disadvantage of

⁸This type of coordinate system is also sometimes referred to as an East North Up (ENU) or East North Height (ENH) coordinate system [Hofman-Wellenhof et al., 1997].

this coordinate system, however, is that it is used only with the City group. For this reason, the position information in the City group's LTP coordinate system is not as useful to people browsing the data from outside the City group, who work in other coordinate systems, as it could be if it were exported in a more well known coordinate system like Earth-Centered Earth-Fixed (ECEF) or latitude-longitude-altitude (LLA) [Hofman-Wellenhof et al., 1997].

Similarly, there is much data generated outside of the City group that would be of use to its members. For example, there exist detailed floor plans and maps of the MIT campus in AutoCAD format, maintained by the Department of Facilities, which could be used to check data derived by the City Group's post-processing algorithms. These maps, and other outside data sources, however, are usually expressed in one of the commonly used cartographic coordinate systems such as US State Plane. Registering the LTP coordinate system with the coordinate systems used in these maps would help the City group validate its data. It could also be beneficial in merging the data we have collected about the building exteriors with detailed information about the building interiors.

There are, of course, limitless other ways that a coordinate transformation library capable of unifying data expressed City group's internal LTP coordinate system and the major coordinate systems used in mapping and surveying could be beneficial. For this reason I have created the Geospatial Coordinate Transformation Library. This coordinate transformation library is a static C++ library which can be linked to any of the City group's existing software or new applications which provides the capability to transform coordinates expressed in an arbitrary LTP coordinate system, such as the one used by the City group, to any of the most widely used geographic, geocentric and cartographic coordinate systems. The coordinate transformation library could be used in conjunction with an open source library (`libgeotiff`, [remotesensing.org, 2000]) for exporting the images in the City Scanning Dataset to GeoTIFF [Ritter and Ruth, 2000], the image format which is becoming the *de facto* standard for encoding geospatial imagery.⁹ Chapter 6 describes the Geospatial Coor-

⁹An extensive source of information about the GeoTIFF format is the official GeoTIFF website:

dinate Transformation Library in detail and supplies the reader with the background information necessary to use it effectively.

1.2.3 Other Minor Extensions and Improvements

This thesis also describes a number of other extensions and improvements to the pre-existing web interface of a smaller scale than that of the DataLink Server and the coordinate transformation library. Each of these is documented in Chapter 7. Among the extensions and refinements added to the pre-existing web interface are:

- A compass visualization in the mosaic viewer and epipolar visualization tools
- The *Sphere View Port*: a small window that shows how points in the planar projection of the sphere texture in the mosaic viewer and epipolar visualization tools map to the cylindrical projection
- Edge and point feature display in the mosaic viewer and epipolar visualization
- Improvements to the epipolar visualization including distance markings on the epipoles
- A Baseline visualization in the mosaic viewer, epipolar viewer and the map viewer
- A Vanishing point visualization in the mosaic viewer, epipolar viewer and the map viewer
- The use of a vector format map in the map viewer, registered with the node data using the coordinate transformation library, and support for arbitrary zoom factors

<<http://www.remotesensing.org/geotiff/geotiff.html>>.

Chapter 2

The DataLink Server

The DataLink Server is designed to facilitate the development of an easily configurable interface for navigating a vast data store on the web. It was created as a step toward fulfilling the desire for a system that abstracts the true organization of the data by providing a pliable set of *virtual* hierarchies which can be tailored to web navigation while at the same time being easily maintainable by a web architect. Folding several logical organizations of the data into one allows a user to explore the full multi-dimensionality of the data space. Such a system should give the user the capability to navigate to the same piece of data though several alternate paths to accommodate for the fact that various users will have different perceptions about what the logical arrangement of the data should be, and it should only provide navigation options for data that is physically present.

The DataLink Server takes several important steps towards realizing this goal. It provides the web developer with centralized, easy-to-modify configuration mechanism: an XML document describing the physical data and the set of valid navigation paths to be made available to users. It also supports a modular front end interface constructed from JSPs, Java servlets and HTML documents called *content handlers*, each of which handles the presentation of data at a particular set of locations within the navigation hierarchy. The DataLink Server has been successfully deployed as the backbone of the City Scanning Project Dataset where it facilitates the navigation of the more than 11,000 geospatial images the City group has collected since the spring

of 2000 and the data we have extracted from them.

2.1 The DataLink Server Maps Virtual Navigation Hierarchies to Real Data

The DataLink Server implements a three-level abstraction of the physical data. The topmost abstraction barrier is created by the *presentation layer*, which is the interface that is visible to the user and is responsible for formatting the data provided by the lower abstraction layers into HTML or other web-browsable content. The next level beneath the presentation layer is the *navigation layer* which is where the navigation hierarchies are defined. The navigation layer describes what data should be visible to the presentation layer at any given point in the navigation hierarchy. It also describes where a user can go to next from the current location in the hierarchy. The navigation layer has a contract with the presentation layer such that it will only provide navigation options for data which is physically present. In order to ensure that this covenant is fulfilled, the navigation layer interfaces with the *data layer* in order to resolve the mappings between the virtual data abstractions in the navigation layer and real physical data in the dataset. The data layer describes the physical hierarchy of the data and defines the *attributes* of each type of datum which might be present in the dataset. Attributes are bits of information such as image resolution, source sensor, date of acquisition or any other properties of which should be presented as selections that the user can use to locate specific data.

Figure 2-1 depicts the interactions between the three abstraction layers of the DataLink Server. As the figure shows, the navigation layer can be thought of as a directed graph, or network, in which each vertex represents a specific location in the navigation hierarchy. Leaf vertices, shown in Figure 2-1 as darkened circles, represent physical resources in the dataset such as images, data files etc. All other vertices in the navigation graph correspond to locations in the virtual navigation hierarchy and may or may not be associated with locations in the physical data hierarchy. A content

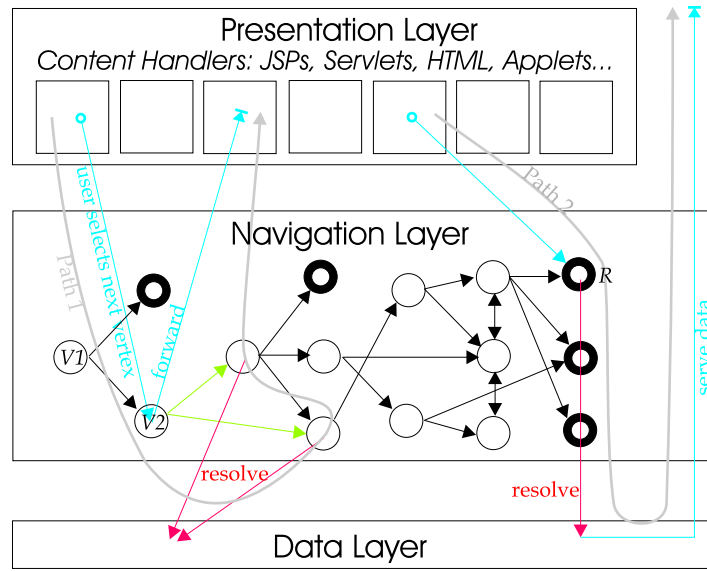

Figure 2-1: Interactions between the abstraction layers of the DataLink Server

handler in the presentation layer may be assigned by the web architect to each non-resource vertex in the navigation network (a default content handler is provided for any vertices for which the web architect elects not create a custom content handler). Edges in the navigation graph tell the DataLink Server what data is visible to the user at a particular vertex in the navigation hierarchy.

The two gray arrows in Figure 2-1 show the primary data paths through the DataLink Server. *Path 1* depicts what happens when a user currently viewing vertex V_1 selects V_2 as the next vertex to display. The user does this by clicking on some link generated by the content handler for V_1 , as suggested by the blue arrow going from the presentation layer to V_2 in the navigation layer. When the user selects the new vertex, the navigation layer must tell the presentation layer what navigation options are available and what data is visible to the user from the new vertex. It does this by examining each of V_2 's children, as illustrated by the green arrows. These child vertices may map to some components of the physical hierarchy. What data they map to is dependent on two things: 1) the data that actually exists in the dataset and 2) the attributes of the current navigation path.

Recall that the data layer defines attributes for each datum in the dataset. Attributes are variables whose values get assigned at runtime, either by selections made by the user or by a pattern matching process that occurs in the data layer, which identify data in the dataset. For example, nodes in the City Scanning Project Dataset are identified by an ID number. If V_2 in Figure 2-1 was used to represent nodes, the content handler for V_1 would probably display links of the form “Node 1”, “Node 2” and so on for every node that exists in the dataset,¹ provided the set of nodes visible to the user at this point was not constrained by other attribute values accumulated along the user’s current path through the navigation graph. The user would move to V_2 in the navigation hierarchy by selecting one of these links. When the user makes one of these selections a value for the `node ID` attribute would be assigned. For example, if the user clicked on the link for “Node 2” `node ID` would bound to the value 2. This value persists as the user descends further into the navigation hierarchy, so if the child vertices of V_2 represent directories for pose data and images then they would only contain the camera files and images that belong to Node 2 in City dataset.

In order to resolve the mappings between the child vertices of V_2 and the physical data in the dataset, given the set of attribute values assigned by the user’s current path through the navigation hierarchy, the navigation layer consults the data layer as is depicted by the red arrows of Figure 2-1. The data layer examines the physical data and returns a set of *branches*-handles to data which map to a given navigation vertex that are consistent with the current set of attributes- to the navigation layer, which in turn forwards these results to the content handler of V_2 . The content handler of V_2 may then display them as links. If the user clicks on one of these links the process is repeated anew for the newly selected vertex.

Path 2 depicts what happens when the user clicks on a link corresponding to a leaf vertex. The mechanism for resolving this data is essentially the same as that described for *Path 1* except that, since a leaf vertex corresponds to a physical resource, such as a file, the data is simply served directly to the user instead of being passed through a content handler in the presentation layer. The action of the navigation layer is also

¹The actual format of the the links is up to the content handler.

minimal in this case. It simply requests the appropriate data from the data layer and then passes it along to the user.

2.1.1 The DataLink Server Can be Accessed Programatically

For simplicity, the previous discussion referred to the client of the DataLink Server as the *user*. However, requests to the DataLink Server are made using the GET or POST protocols, which means that the DataLink Server can also be accessed programatically like a CGI application. This gives content handlers or other web applications the ability to locate data within a dataset “behind the scenes” in order to generate more dynamic content without any code for locating physical resources being hard-wired into the actual web content. The DataLink Server package includes a Java API which can be used to create properly formatted requests for items in the navigation hierarchies given an appropriate set of attributes. Section 4.4 and Appendix A give the complete details of the API for formatting requests to the DataLink Server. As we’ll see in Section 5.2 the typical format for DataLink Server requests using the GET protocol looks like:

```
DataLink?view=node&dataset=all-nodes&nodeId=11&history=dataset:all_nodes
```

2.2 Components of the DataLink Server

The DataLink server is comprised primarily of five discrete components. This modular architecture is essential to achieve the high degree of customizability provided by the DataLink Server. All of these components interface with one central application, the `DataLinkServlet`, which handles the processing of requests. Only the `DataLinkServlet` itself and the software behind its API are off-limits to developers. All of the other components are created or extended by web developers to implement a custom web application. The idea is that the web developers only have to describe how the web site should be laid out as well as what functionality it should provide, and the DataLink Server infrastructure should take care of the rest. The follow-

ing sub-sections describe each of the essential components of the DataLink Server in detail.

2.2.1 Data and Navigation Models Define the Abstraction

The abstraction function provided by the DataLink Server is defined by a pair of directed graphs called the *navigation model* and the *data model*. Section 2.1 and Figure 2-1 have already given some sense of the nature of the navigation model. As we have seen so far, the navigation model consists of vertices which represent locations in the virtual navigation hierarchies. Most of these vertices really represent some type of datum in the physical dataset. This data type may be a resource, such as an image or a data file type, or, it may be a type of vertex in the physical data hierarchy, such as one of the node directories that contains all of the data for a particular node in the City dataset. Navigation vertices, however, need not correspond to a real physical datum at all. They may simply exist for the purpose of guiding the user's navigation by assigning values to attributes, or they may be used for generating a particular view of some subset of the data.

The navigation model is coupled with the *data model* to resolve the mapping between the virtual data hierarchies and the real physical data. Vertices in the data model correspond to items in the dataset. Edges in the data model graph describe the hierarchical relationships between these elements. In particular, if there is an edge from data vertex V_1 to data vertex V_2 then V_1 *inherits* the attributes of V_2 . Every vertex in the data model is an instance of a *data vertex type*. Each unique kind of datum in the dataset is represented by its own data vertex type whose definition contains information about the names and types of attributes associated with that particular datum. There may be multiple instances of a single data vertex type in the data model.

The illustration in Figure 2-2 should help to clarify how the navigation model and data model abstractions work together. Figure 2-2 shows a simple set of models that describe the web interface to an imaginary classical music library. On disk, the physical hierarchy of the library consists of a root directory which holds a subdirectory for

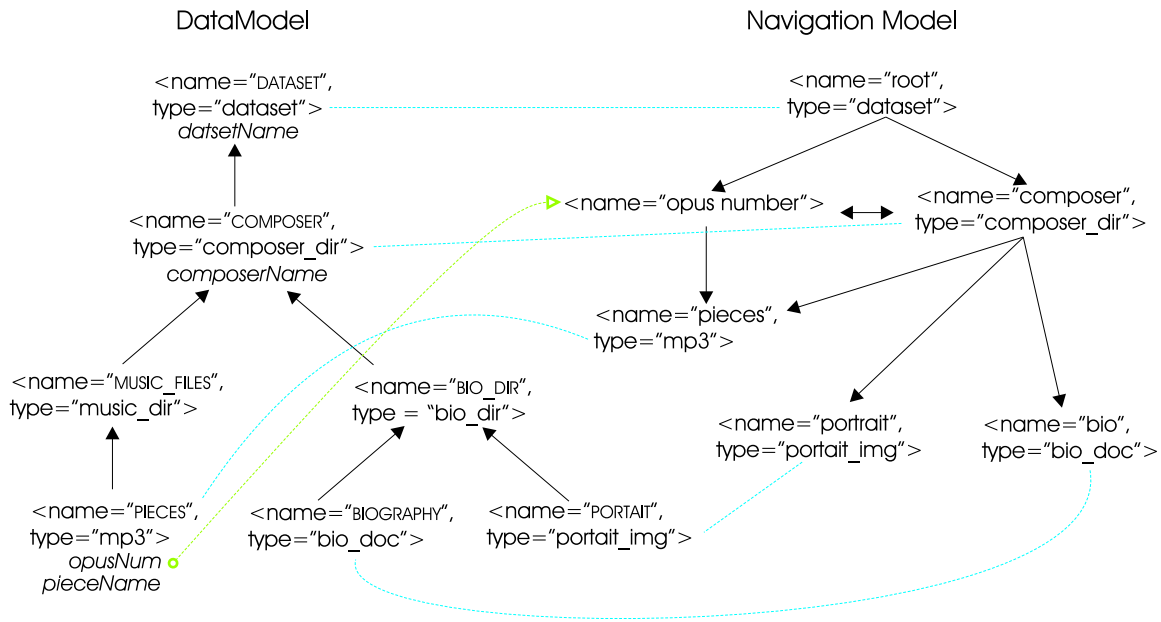

Figure 2-2: A simple set of models for a classical music library

each composer in the library.² Each composer directory contains two subdirectories. One is a “biography” directory which holds a document about the life of the composer and an image of the composer’s head. The other is a “music” directory which contains audio files of pieces written by the composer.

The navigation model re-maps this directory structure to a slightly different set of hierarchies. The user can begin browsing the dataset by selecting the name of a composer, causing the system to visit the `composer` vertex. Once that selection is made the user will see a listing of pieces penned by the selected composer as well as a biographical sketch and a mug-shot. Clicking on the name of a piece will then download that recording. An alternative route that the user could take through the dataset is to begin by selecting the opus number of a piece to find. This would take

²The data models discussed in this document will typically be models of directory trees. This is a reflection of the first target application of the DataLink Server: purveying the navigation infrastructure for the City Scanning Project Dataset, which is stored in an elaborate directory structure. It should be noted, however, that the data model is merely an abstraction and that, although the software implementing this abstraction is tailored to modeling directory trees, it would be easy to extend the data model to provide an interface to any hierarchical data storage system, such as a database.

the user to the `opus number` vertex. Figure 2-2 does not completely specify what the behavior of the system should be at this point, but there are two possibilities: 1) The system could display link for every piece in the dataset with the selected opus number as well as a link for every composer in the dataset. 2) The system could display only the the links to the composer branches and omit the links to the audio files because the attributes accumulated along the path traversed thus far are not enough to completely specify the path to any piece of music. It is possible to configure navigation vertices with either behavior.

Before reading any further, be sure to note that the edges in the data model and navigation model graphs point in opposite directions. In Figure 2-2 the edge going from the `PIECES` data vertex to the `MUSIC_FILES` vertex indicates that `MUSIC_FILES` is the *parent* directory of the audio files which correspond to `MUSIC_FILES`. This means that pieces inherit all the attributes of `MUSIC_FILES`, `COMPOSER` and `COMPOSER_DATASET`, the ancestor vertices of `PIECES`, so a piece in the classical music library has values for the `datasetName`, `composerName`, `opusNum` and `pieceName` attributes (In Figure 2-2 the attributes for a given data vertex type are listed under each instance of that vertex type). The edge from the `opus number` navigation vertex to the `pieces` vertex³ in the navigation model, on the other hand, means that `pieces` is the *child* of `opus number`; any audio files visible to the user located at vertex `opus number` in the navigation hierarchy must have the same opus number as the branch of `opus number` that the user selected to view.

The reason for this disparity is that it makes the implementation of the models in the DataLink Server much simpler and more efficient. Chapter 5, which discusses the implementation of the DataLink Server, will elucidate the logic behind this design, but, for now, the basic intuition is that the user will *navigate* a hierarchy from the top down, accumulating attributes which make the subset of the data in consideration

³Throughout this thesis I have adopted the convention that data vertex names will be written in UPPERCASE whereas navigation vertex names will be completely lowercase in order to differentiate between data and navigation vertices which have the same names. The names of vertices in the actual model files do not have to adhere to this convention, and they may contain any virtually any character apart from some special characters which are described in Chapter 3.

more and more narrow. When trying to map attributes to physical data in the data model, however, the system will never be concerned with the children of a vertex. Instead it will need to examine the vertex's ancestors in order to determine the attributes it may have, or it may have to enumerate the ancestors to reconstruct a path to the physical data.

Interactions Between the Data and Navigation Models

The dashed blue lines in Figure 2-2 show one way in which the navigation model interfaces with the data model to retrieve the physical data. The specification for navigation vertices which map directly to physical data in the data model include a **type** field which gives the name of the corresponding data vertex type in the data model. When the navigation layer explores a child vertex of the currently selected vertex (as shown by the green arrows in Figure 2-1) which is mapped to a data vertex type, T , to see which elements of type T (if any) should be made visible to the presentation layer, it makes a request to the data layer for all branches of type T which are consistent with the current set of attribute values. The data layer then looks for every instance of data vertex type T in the data model, and examines its ancestry to construct a chain of data vertices from each matching data vertex to the a root vertex in the data hierarchy.⁴ The set of chains revealed by this process describes all of possible paths to data of type T . The data model then returns a set of complete attribute bindings for all the paths in this set which are consistent with the attribute values specified by the navigation layer.

For example, suppose our music library contained only four pieces: the Brahms sonatas for clarinet and piano no. 1 and no. 2 op. 120, Beethoven's symphony no. 2 op. 36 and Vivaldi's *The Four Seasons* op. 8. Selecting the branch of navigation vertex **composer** for "Brahms" from the **root** vertex would define the current set of attribute bindings to be `{composer = "Brahms", datasetName = "classical"}`. The navigation layer would then examine each of the child vertices of **composer** to determine

⁴There is no restriction on the number of root vertices that may exist in the data model.

the next set of navigation options that should be made available to the user. To discover the possible options for vertex `pieces` the navigation layer would request the set of all branches for data vertex type `mp3` for which `composer = Brahms` from the data layer. The data layer would then look in the data model for instances of vertex type `mp3` and find only one, `PIECES`. The chain for the `PIECES` vertex looks like `PIECES → MUSIC_FILES → COMPOSER → DATASET` which, given the current attribute values, expands to a the path `/classical/Brahms/music_files/Brahms-*-op.*.mp3`, where the asterisks denote the unknown values of the `pieceName` and `opusNum` attributes.⁵ The data layer matches this path to the two Brahms pieces in the dataset and returns the following sets of attribute bindings as the possible branches for the `PIECES` vertex: `{composer = "Brahms", datasetName = "classical", pieceName = "Sonata for Clarinet and Piano no. 1", opusNum = 120}` and `{composer = "Brahms", datasetName = "classical", pieceName = "Sonata for Clarinet and Piano no. 2", opusNum = 120}`.

Another way which the navigation model might synchronize with the data model for vertices that *do not* map directly to data vertex types is illustrated by the green arrow in Figure 2-2. This arrow depicts the `opusNum` attribute being *promoted* to a higher level in the navigation hierarchy. When the navigation layer explores the `opus number` vertex it will try to determine all possible values for the promoted `opusNum` attribute, given the current set of attribute values. It will do this by consulting with the data layer about the possible values for this attribute in a way that is analogous to requesting all valid branches for the `PIECES` vertex and extracting from this the set of all possible values for the `opusNum` attribute, each of which will be presented as a distinct navigation option to the user.

The Models are Defined Using XML

The models for a particular dataset are defined in an XML document which is completely separate from the rest of the DataLink Server. The model definition file

⁵The details about how the DataLink Server maps attribute values to directory and file names will be given in Chapter 3.

functions as a configuration file for the DataLink Server which is used to “bootstrap” it with the abstraction function for a particular dataset, so configuring the DataLink Server for a new dataset is chiefly a matter of writing a model file for the new dataset. In addition, modifying the layout of an existing site is as simple as altering a few vertex definitions in the model file. The beauty of this mechanism is that alterations to the layout of web interface don’t require rewriting the hyperlinks, HTML documents and scripts that make up the front-end of the interface in order to re-wire the website because DataLink Server follows the specification in the model file to do all of this automatically. Also, data can be added to or removed from the dataset without the need to regenerate any part of the web site’s infrastructure since all of the navigation options are determined dynamically. The content handlers to be used for each navigation vertex are also specified within the model file. Chapter 3 will have more to say about the navigation and data model abstraction and the XML-based modeling language that is used to define them.

2.2.2 The Core of the DataLink Server is the DataLinkServlet

At the heart of the DataLink Server is the `DataLinkServlet` Java servlet, which provides the navigation/data location infrastructure needed to drive a web interface based on the specification captured in the model file. The `DataLinkServlet` is backed by two components, the `DataModel` and the `NavModel` which are software representations of the data and navigation models from the model definition file. The `DataModel` and the `NavModel` are the modules of the DataLink Server which implement the data and navigation layers respectively. A block diagram of this architecture is shown in Figure 2-3. The detailed inner-workings of the `DataLinkServlet`, the `DataModel` and the `NavModel` are related in Chapter 5.

2.2.3 The Front End Consists of Content Handlers

As mentioned earlier, the presentation layer is controlled by content handlers which may be Java server pages, servlets or HTML documents (for static content). Content

Figure 2-3: Architecture of the DataLink Server

handlers give the web designer freedom to customize the look-and-feel of the web interface and flexibility in controlling the way the data is presented to the user. A content handler could simply present links to the raw data, much like a directory listing or it may incorporate Java applets, Javascript, DHTML or other means to make the data interactive. As Figure 2-3 demonstrates, the content handlers sit on top of the `DataLinkServlet` architecture.

Figure 2-4 shows the document the content handler for the `composer` vertex in the classical music dataset might produce for the branch `{dataset="classical", composerName = "Brahms"}`. As the figure shows, the data for the `portrait` and `bio` vertices are incorporated into the output document itself, whereas hyperlinks, whose action is to dispatch a query to the `DataLinkServlet` for a particular branch of the `pieces` vertex, are provided for the user to download the audio files.⁶ Figure 2-5 shows the output of the content handler for the `node` vertex (which maps to a node directory) in the City dataset. This content handler makes use of many interactive elements such as Java applets for viewing the spherical texture, a clickable map applet for browsing through the other `node` branches and cascading Javascript menus which allow the user to jump to sibling vertices of those in the current navigation path.

⁶The biographical text used in this example is an excerpt from *Music: An Appreciation* by Roger Karmien, pp. 256-258 [Karmien, 1999].

[Sonata for Clarinet and Piano no. 2 op. 120](#)

Biography

"Johannes Brahms (1833-1897) was a romantic who breathed new life into classical forms. He was born in Hamburg, Germany, when his father made a precarious living as a bass player. At thirteen, Brahms led a double life: during the day he studied piano, music theory, and composition; at night he played dance music for prostitutes and their clients in water front bars.

"On his first concert tour, when he was twenty, Brahms met Robert Schumann and Schumann's wife Clara, who were to shape the course of his artistic and personal life. The Schumanns listened enthusiastically to Brahms's music, and Robert published an article hailing young Brahms as a musical messiah.

"As Brahms was preparing new works for an eager publisher, Schumann had a nervous collapse and tried to drown himself. When Schumann was committed to an asylum, leaving Clara with seven children to support, Brahms came to live in the Schumann home. He stayed for two years, helping to care for the children when Clara was on tour and becoming increasingly involved with

Images

The images you see on this page constitute one node from the City Scanning Project dataset. The raw images seen at the bottom of this page share a common optical center but are rotated into various orientations that together tile a hemisphere. During the mosaic stage of post processing, these images are more accurately aligned with each other and combined to form the spherical texture seen above. The spherical texture is better viewed using the **Mosaic Viewer** at the right, which allows you to view the node from its optical center and rotate the viewing angle along the horizontal and vertical axes.

The images in the *City Scanning Project Dataset* are all high dynamic range (HDR) images. Although the images are encoded using the lossless SGI .rgb format, with color values ranging from 0-255, these values actually represent the log of the true radiance values. The following equation captures the relationship between the .rgb pixel values and the corresponding

Figure 2-5: A screen shot of the content handler for the node vertex of the City dataset

The API for Writing Content Handlers

The DataLink Server package provides two crucial classes for interfacing with the `DataLinkServlet` that facilitate writing content handlers. The `DataLinkDispatcher` class implements about 20 static methods for formatting requests to the `DataLinkServlet` and processing the data returned by it. These include methods for sorting branches, opening streams to resource files via the `DataLinkServlet` and formatting URLs or hyperlinks that access `DataLinkServlet` given a set of attribute values, which may be encoded in one of several different types of data structures.

The DataLink Server also includes a class for formatting special context navigation menus, `BranchHistoryScripter`, for use in content handlers. The menus created by this class are activated by mousing over the name of one of the branches visited along the user's current path through the navigation hierarchy, which are listed at the top of the page, or wherever the author of the content handler decides to place them, and enumerate all of the other alternative branches the user could have chosen at that point in the path. Selecting one of these options jumps to that branch. In the sample screen in Figure 2-5 the user has activated the context menu for the `node` branch.⁷ The complete documentation of the `DataLinkDispatcher` and the `BranchHistoryScripter` are located in the chapter devoted to content handler development: Chapter 4.

⁷There are more than 500 nodes in the City dataset, which is why the context navigation menu for nodes only lists two options: one for the currently selected node and one which warps the user back to the next higher level in the hierarchy, the `dataset` vertex, in order to choose another. When there are only a few alternatives the menus can display them all. Parameters in the model file allow the developer of the web site to specify which of these alternatives is appropriate for a given navigation vertex. As is to be expected, there are performance issues associated with allowing the full listing capability for vertices which could potentially have a large number of branches.

Chapter 3

Modeling Data and Directing Navigation Using XML

In this chapter you will learn about the XML-based modeling language for describing a dataset and controlling the behavior of the navigation layer of the DataLink Server. You will learn how a data model describes how to extract the salient properties of the data from a hierarchical dataset, as well as how the navigation layer uses the attributes of the data as the pivots about which navigation is guided. You will see how the navigation model outlines the behavior of the navigation layer and how it determines the type of information that is passed to the presentation layer. Each of the modeling constructs in this chapter is illustrated with concrete pedagogical examples or real samples from the City dataset, and, by the end of it, you will have acquired all of the knowledge necessary to begin designing the architecture of powerful web gateways to large datasets.

3.1 The Model Definitions are Described in XML

The modeling constructs used to control the DataLink Server are written in XML¹. XML was chosen as the basis of the modeling platform in lieu of some custom language

¹The definitive resource on XML is *Extensible Markup Language (XML)*, [The World Wide Web Consortium, 2002a], <<http://www.w3.org/XML/>>.

and file format because it has a number highly desirable qualities that make it ideal for this application. One property, in particular, that makes XML a good candidate for the job of defining the models is that its structure, consisting of elements that are localized within the context of other parent elements, closely parallels the directed graph structure of the models themselves. In fact, when an XML document is parsed, the data structure that is produced is a tree. Other features of XML which make it an excellent choice for this task are:

- Powerful XML parser distributions are available in Java and C++.²
- Error checking and reporting for an XML file is automatic when it is coupled with a validating parser and a document type specification such as an XML schema³ or a DTD.⁴
- The use of a markup language makes the models file easy to read and comprehend.
- The syntax of a model file written in XML will be familiar and intuitive to any developer who has experience with one of the markup languages in the SGML family, including XML and HTML.

3.2 A Block Level Description of the Model File

The model file consists of two major sections, one which describes the data model and one which describes the navigation model. The data model block consists of section in which the types of vertices which can exist in the data model are defined and a

²The parser chosen for the DataLink Server is the Apache Xerces XML parser. This parser was chosen because it adheres to the standard XML specifications issued by the World Wide Web Consortium (W3C, <<http://www.w3.org/>>). It is available in both C++ and Java, which makes porting applications to different language environments easier. Also, it is free and open source. Xerces distributions and documentation are available for download from the Apache XML Project website, <<http://xml.apache.org/>>.

³See *XML Schema* [Sperberg-McQueen and Thomson, 2002], <<http://www.w3.org/XML/Schema/#dev>>

⁴See [The World Wide Web Consortium, 2002a]

section which describes how instances of these vertex types are connected together to construct a model of the physical data. The navigation model block contains definitions of all the navigation vertices in the navigation model and a specification of how all of these vertices are connected. A skeleton of the model file looks like:

```
<?xml version="1.0" encoding="UTF-8"?>

<modelDefs xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:no
NamespaceSchemaLocation="http://city.lcs.mit.edu:8080/data2/models/mode
ls.xsd">

  <!-- data model block: -->
  <dataModel>

    <!-- This URI specifies where the dataset lives: -->
    <home href="/" />

    <!-- This is where the data vertex type definitions should go. -->

    <!-- This is where the data vertex instances are created. -->

  </dataModel>

  <!-- navigation model block: -->

  <navModel>

    <!-- Here we define the navigation vertices. -->

  </navModel>

</modelDefs>
```

This code listing shows the where the two principal blocks of the model file belong. The `modelDefs` element is the root element of the model file. Contained within it are the `dataModel` and `navModel` elements, which encapsulate the data model and navigation model definitions (the term *element* refers to a construct of the form `<element>element data</element>`).

Character	Use	Restricted From
<code>&</code>	GET request URLs	navigation vertex names and attribute names
<code>=</code>	GET request URLs	navigation vertex names and attribute names
<code>:</code>	delimits history elements in DataLink Server requests	navigation vertex names

Table 3.1: Reserved characters

3.2.1 An XML Schema is Used For Validation

In the previous example the `modelDefs` element references an XML schema file, `<http://city.lcs.mit.edu:8080/data2/models/models.xsd>`, which encodes the definition of the model file format. When the model file is parsed, this schema is used to check and report errors in the model file's structure and syntax. To ensure that errors are properly reported during parsing, a reference to this schema should be included in every model file. A complete listing of model file schema is located in Appendix B.

3.2.2 Reserved Characters

In general, vertex and attribute names in the model file can contain any character, including spaces. Some of the special characters used in requests to the DataLink Server will cause problems if they are used in attribute or vertex names. Table 3.1 lists these characters and summarizes the contexts in which they are reserved.

3.3 Creating a Data Model

This section describes how to model a hierarchical dataset. The example datasets in this document will be directory hierarchies because the current implementation of the `DataModel` class is geared towards modeling directories. This is a reflection of the first target dataset of the DataLink Server, the City Scanning Project Dataset, which is kept on disk in an elaborate directory structure. It should be noted, however, that the data model is merely an abstraction and that, although the software implementing

this abstraction is tailored to modeling directory trees, it would be easy to extend the data model to provide an interface to any hierarchical data storage system, such as a database. With that in mind, it's time to being learning how to write a data model.

3.3.1 Data Vertex Type Definitions

Before describing how the the various elements of the data hierarchy are related, it is first necessary to define all of the different types of data that might be found in the dataset. As mentioned earlier, this is accomplished with data vertex type definitions, which have the form:

```
<vertexType name="data vertex type name">
  <!-- Attribute definitions go here: -->
  <attributes>
    <!-- integer attribute definitions -->
    <!-- string attribute definitions -->
    <!-- state attribute definitions -->
  </attributes>

  <!-- data signatures go in this section -->
</vertexType>
```

As this outline shows, a data vertex may contain attribute definitions of three types, *integer* attributes, *string* attributes and *state* attributes and one or more *signature* definitions, which tell the DataLink Server how to recognize a datum of this data type. A data vertex type element can have zero or more attribute definitions of each of the different attribute types, but the attributes must appear in the same order they are listed in the `vertexType` outline, above. That is to say, all the integer attribute definitions must appear first, the string attributes must appear next, and the state attribute definitions must be last. This is an artifact of the XML schema language that is used to define the model document type, which has no construct for unordered element groupings in which each element of the group may appear more than once. This restriction is not terribly inconvenient as long as one remembers

it when writing model files. In point of fact, this rule carries throughout any XML document; the elements must appear in a fixed order.

Attribute Definitions

There are two components to every attribute construct: a type declaration and a name. In essence, attributes are declared in the same way as variables are in any programming language. Attribute names can consist of any character sequence that does not include the & or = characters. In addition, attribute names cannot be one of the three keywords which are used in requests to the DataLink Server: **view**, **resource** and **history**.

Integer Attributes True to their name, integer attributes can hold any integer value. Integer attribute definitions have the form:

```
<int name="attributeName"/>
```

String Attributes The value of a string attribute can be a character sequence of any length. String attribute definitions look like:

```
<string name="attributeName"/>
```

State Attributes State attributes are a little more complicated than string and integer attributes. State attribute definitions look like:

```
<stateVar name="attributeName">
  <!-- abstract states: -->
  <state name="abstract state name 1">
    <signature>state 1 signature</signature>
  </state>
  <state name="abstract state name 2">
    <signature>state 2 signature 1</signature>
    <signature>state 2 signature 2</signature>
  </state>
</stateVar>
```

A state attribute can assume any one of a discrete set of *abstract states*. The abstract states are defined by `<state>` elements inserted within the body of the state attribute definition. Every abstract state declaration must include at least one `<signature>`. A *signature* is a character pattern that the data link server uses to identify items in the physical data. A signature is a pattern which matches a filename, or part of a filename, in the case of state attributes. These state signatures are basically keywords used by the data layer to determine the abstract state of state attributes from properties of the physical data. If the value of a state attribute extracted from a filename matches a particular signature of abstract state *a*, then the data layer knows that the abstract state of the attribute is *a*. To see how this works, let's examine an example from the City dataset.

Recall from Section 1.1.1 that after a City Scanning node is acquired, it enters a pipeline of post-processing stages. Each of these stages improves the position and orientation information associated with each image in the node and outputs a new, refined set of camera files for those images. The camera files for each post-processing stage are stored in a directory named after that stage, such as `initial`, `mosaic` etc. A state attribute of the `pose_refinement` data vertex type, which represents one of these pose directories, is used to make the data's state of post-processing refinement a navigable property:

```
<vertexType name="pose_refinement">
  <attributes>
    <stateVar name="refinement">
      <state name="initial"><signature>initial</signature></state>
      <state name="mosaiced"><signature>mosaic</signature></state>
      <state name="rotated"><signature>auto_rot</signature></state>
      <state name="translated">
        <!-- signatures searched in the order listed here: -->
        <signature>all_trans</signature>
        <signature>trans_set4</signature>
      </state>
    </stateVar>
  </attributes>
  <signature>"%t", refinement</signature>
</vertexType>
```

As you can see, the `refinement` attribute has four abstract states, `initial`, `mosaiced`, `rotated` and `translated`, representing the four possible states of post-processing refinement. These abstract state names are not identical to the names of the pose refinement directories from which they get their values, `initial`, `mosaic`, `auto_rot`, `all_trans` and `trans_set4`, but the `<signature>` declarations map the abstract states to the appropriate directory names. The precise definition of this mapping is given by the `pose_refinement` vertex's signature, `<signature>"%t", refinement</signature>`. Make note that the vertex's signature is different thing than state attribute signatures. In this example, the vertex signature is a pattern specifier which says that a `pose_refinement` directory's name is equal to the value of the state attribute `refinement`. Whatever *state* signature this value matches determines the abstract state of the `refinement` attribute. The next section will explain this mechanism in detail, but the important thing to glean from this discussion is that, according to the above vertex definition, when the `refinement` attribute has the value `auto_rot`, the DataLink Server recognizes `rotation` as the abstract state of the `refinement` attribute, and similarly for the other states and state signatures.

Notice that the `translated` state has two signatures, `all_trans` and `trans_set4`. This is because the City scanning dataset contains data from multiple runs of the post-processing algorithms.⁵ Instead of overwriting the old data each time the algorithms are run, the author of the new data may sometimes rename the old directories for safe keeping. As a byproduct of this practice, there are some nodes in the City dataset whose translated camera files are stored in `all_trans` directories, some whose translated data are stored in `trans_set4` directories and some nodes that have both `all_trans` and `trans_set4` directories.

In general, when the DataLink Server is searching for data with an abstract state that has more than one signature, it gives precedence to data with the signature that appears first in the `<state>` declaration, so, for nodes with both `all_trans` and

⁵As new data is acquired, the post-processing pipeline is often reapplied to the entire dataset in order to take advantage of any new global features, such as vanishing points and baselines, that have been discovered in the new nodes.

Example	Abstract State	Literal State
unbound	null	null
extracted from <code>auto_rot</code> datum or requesting <code>auto_rot</code> data	<code>rotated</code>	<code>auto_rot</code>
in request for rotated data	<code>rotated</code>	null

Table 3.2: Valid state pairings listed by example

`trans_set4` directories, the DataLink Server will return the contents of the `all_trans` directory when it receives a request for camera files in the `translated` abstract state of pose refinement. It is possible to make requests to the DataLink Server which override this behavior in order to obtain camera files from only the `trans_set4` directories or vice versa.

State Attributes Have Abstract and Literal Values State attributes can hold two types of values simultaneously, an *abstract* state and a *literal* state. The literal state of a state attribute is the particular state signature that it is bound to. When state attributes are extracted from physical data they will have both a literal state, which was obtained from the data itself, and a corresponding abstract state. When making requests to the DataLink Server, the client may only be interested in the abstract state of the data, so, in this case, it will make a request with only the abstract state of the state attribute defined. In other cases, such as when the client wants to make a request for only the `trans_set4` data, it may make a request with the literal state of the `refinement` attribute specified. Table 3.2 lists some examples using the `refinement` attribute which illustrate each of the possible value pairings a state attribute may assume.

Data Vertex Type Signatures Define the Mapping of Attributes and Data

Data vertex type signatures define the mapping between attributes and physical data and, conversely, tell the DataLink Server how to derive attribute values from an instance of a data type in the dataset. This example vertex from the City Scanning Project Dataset should help to illustrate how signatures work:

```

<vertexType name="image">
  <attributes>
    <int name="imgId"/>
  </attributes>
  <signature>"%4d.rgb", imgId</signature>
</vertexType>

```

This sample is the data vertex type definition for an image in the City dataset. Each node in the City dataset consists of a collection of numbered .rgb images with filenames of the format 0000.rgb, 0001.rgb etc. The four-digit number in the name of each image is the image's ID, which is captured by the `imgId` attribute of the `image` data vertex type. The signature that maps the four digit image ID in the image's filename to the `imgId` attribute is simply a C-style string format expression with the token `%4d` in the place of the image ID number.⁶ The signature expression indicates that the value of this token is equal to the value of the `imgId` integer attribute.

String format expressions like these are all that is necessary to extract the salient attribute values from file and directory names in a directory hierarchy. Although it was not necessary for the City Scanning Project Dataset, a similar mechanism could be added to the data model for extracting attribute values from data actually stored *within* the data files themselves, and it would not be much of a stretch to add a parallel construct for obtaining attribute values from database keys.

Table 3.3 lists the tokens that can be used in signature expressions. Most of these are identical to their counterparts in C. In addition I have added two new tokens, `t` and `T`, for formatting state attributes.⁷

It is not uncommon to find datasets with inconsistent naming schemes. To combat this problem, the DataLink Server supports the capability to define multiple signatures per data vertex type. As is the case for state signatures, the DataLink Server

⁶This discussion assumes the reader is familiar with the syntax of C string format expressions. However, for a reference or a quick review, look in any C/C++ guidebook. I recommend *C++: The Complete Reference [Schildt, 1995]*.

⁷The current implementation of the DataLink Server does not support the full gamut of format tokens that C programmers may know about (there was no need for floating point attributes in the City dataset), but the string format expression code is modular enough that format tokens for new data types can be added without tribulation. Other than the floating point tokens, most of the other C format tokens can be subsumed by the `d` token, anyway. In addition, there is no support for the hexadecimal format modifier, `#`, and I do not foresee there ever being a need for the `*` modifier.

Attribute Type	Format Token
int	%d
string	%s
stateVar (abstract state)	%T
stateVar (literal state)	%t

Table 3.3: String format expression tokens used by the DataLink Server

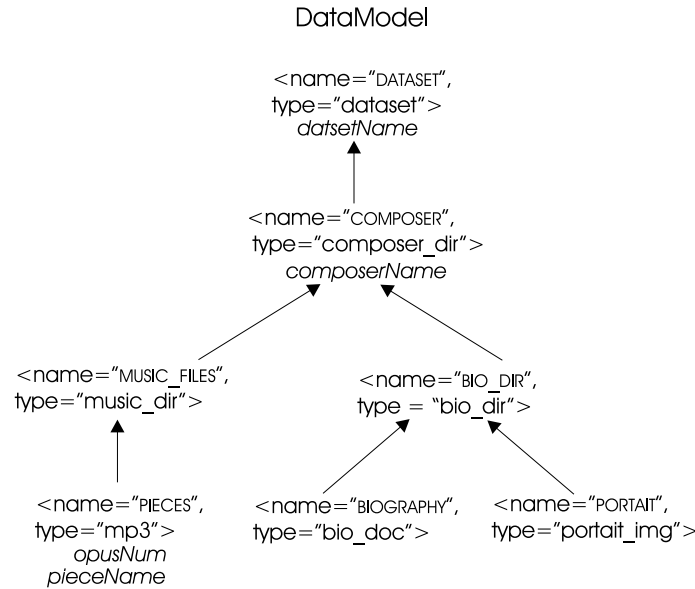

Figure 3-1: Data model of a classical music library

will give preference to the data vertex type signature which appears first in the body of a data vertex type definition.

3.3.2 Declaring Data Vertex Instances

Now that that the tools for describing the data have been garnered, it's time to learn how to declare instances of these data types and connect them together to form the data model graph. An example is the best way to demonstrate how to do this, so let's begin by seeing how we would create a data model for the classical music dataset from Chapter 2 (A diagram of this dataset is duplicated for convenience in Figure 3-1): First, let us use the information from the previous section to create an explicit definition of the data itself:

```

<dataModel>
  <!-- This URI specifies where the dataset lives: -->
  <home href="/usr/local/music_libs"/>

  <!-- data vertex types: -->

  <!-- dataset directory: -->
  <vertexType name="dataset">
    <attributes>
      <string name="datasetName"/>
    </attributes>
    <signature>"%s", datasetName</signature>
  </vertexType>

  <!-- composer directory: -->
  <vertexType name="composer_dir">
    <attributes>
      <string name="composerName"/>
    </attributes>
    <signature>"%s", composerName</signature>
  </vertexType>

  <!-- music directory: -->
  <vertexType name="music_dir">
    <signature>"audio_files"</signature>
  </vertexType>

  <!-- biography directory: -->
  <vertexType name="bio_dir">
    <signature>"bio"</signature>
  </vertexType>

  <!-- audio file: -->
  <vertexType name="mp3">
    <attributes>
      <int name="opusNum"/>
      <string name="pieceName"/>
    </attributes>
    <signature>"%s-%s-op. %d.mp3", composerName, pieceName, opusNum</s
signature>
  </vertexType>

  <!-- biography file: -->
  <vertexType name="bio_doc">
    <signature>"%s.txt", composerName</signature>

```

```

</vertexType>

<!-- picture of composer: -->
<vertexType name="protrait_img">
  <signature>"%s.jpg", composerName</signature>
</vertexType>

<!-- This is where the data vertex declarations will go. -->

</dataModel>

```

This data model says that our music library is contained within a directory with some name like, “classical” which should be stored in the `datasetName` attribute. Inside this directory are some subdirectories such as `Johannes Brahms`, `Modest Mussorgsky` etc., which are named after the composers in the library. In each composer directory there are two subdirectories with fixed names: `audio_files` and `bio`. Each `bio` directory contains a biography file and a portrait of the composer, and held within each `audio_files` directory are the pieces written by composer, whose filename is constructed from the composer’s name followed by the title of the work and the opus number (i.e. `Johannes Brahms-Sonata for Clarinet and Piano no. 1-op. 120.mp3`). Notice that attributes are declared at the highest level of the hierarchy in which they appear, and declarations for them are omitted from vertex type definitions for data that lie beneath this node in the data hierarchy. This is because when instances of these data vertex types are connected together to form a graph, these attributes will be inherited. Let’s do that now:

```

<dataModel>
.
.
.

<!-- data vertex declations: -->

<vertex name="DATASET" type="dataset"/>
<vertex name="COMPOSER" type="composer_dir">
  <parent name="DATASET"/>
</vertex>

```

```

<vertex name="MUSIC_FILES" type="music_dir">
  <parent name="COMPOSER"/>
</vertex>
<vertex name="BIO_DIR" type="bio_dir">
  <parent name="COMPOSER"/>
</vertex>
<vertex name="PIECES">
  <parent name="MUSIC_FILES"/>
</vertex>
<vertex name="BIOGRAPHY">
  <parent name="BIO_DIR"/>
</vertex>
<vertex name="PORTRAIT">
  <parent name="BIO_DIR"/>
</vertex>
</dataModel>

```

See how the `parent` command has been used to specify the edges in the data model? That's all there is to it. The structure of the `vertex` element has left open the possibility of vertices having more than one parent. This is not currently supported by the DataLink Server because allowing only one parent per vertex greatly simplifies the computational complexity of the algorithms used in the DataLink Server's implementation (see Chapter 5). Room has been left in the DataLink Server code for the possibility of this extension, however.

3.4 Writing a Model To Direct Navigation

Now that you know how describing the data is accomplished you can learn how to make it navigable. This is the purpose of the navigation model block of the model file, which describes the interconnections between a network of navigation vertices. The basic outline of a navigation model looks like this:

```

<navModel>
  <!-- navigation vertex declarations go here. -->

  <root name="name of root navigation vertex"/>

```

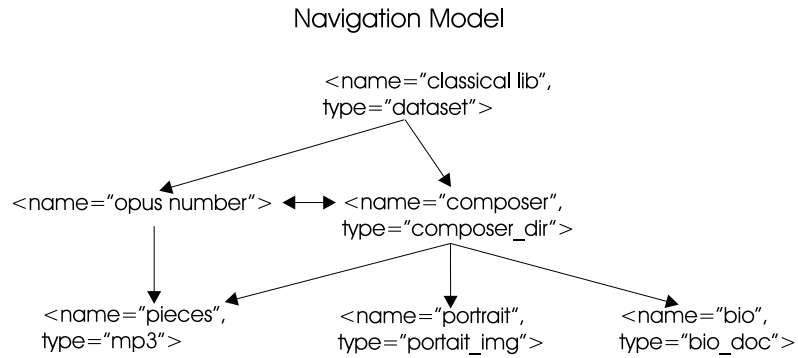

Figure 3-2: Navigation model of the classical music library

```
</navModel>
```

3.4.1 Defining Navigation Vertices

Enumerating a list of all the features involved in creating a navigation model would be tedious to read and far less trenchant than a series of demonstrative examples, so, in that light, we will continue this discussion of navigation models by building one for the classical music library. The basic structure of the navigation model we will build is shown in Figure 3-2. After detailing how this navigation model is put together, this section will show how additional parameters of navigation vertices can be used to fine tune the DataLink Server's exhibition of this model.

The best way to design a navigation model is from the bottom up starting with vertices for the files to make available:

```

<navModel>
.
.
.
<vertex name="pieces" type="mp3"/>
<vertex name="portait" type="portait_img"/>
<vertex name="bio" type="bio_doc"/>
.
.
.
</navModel>

```

This exposes the images, biography text documents and audio files to the navigation layer by assigning navigation vertices to them. The **type** argument grounds each of these vertices to the appropriate data vertex type in the data model. When the navigation layer explores a navigation vertex with a **type** declaration, it knows to ask the data layer for instances of that data type. As it stands, however, this navigation model doesn't provide any way of reaching this data because no navigation paths have been specified yet. The following code listing adds a simple one:

```
<navModel>
  <vertex name="classical lib">
    <child name="composer"/>
  </vertex>
  <vertex name="composer" type="composer_dir">
    <child name="pieces"/>
    <child name="portrait"/>
    <child name="bio"/>
  </vertex>
  <vertex name="pieces" type="mp3"/>
  <vertex name="portrait" type="portrait_img"/>
  <vertex name="bio" type="bio_doc"/>

  <root name="classical lib"/>
</navModel>
```

The path described here begins at the vertex named `classical lib`, as specified by the `root` command. From here the user will be allowed to select a composer directory to view. The DataLink Server will present a composer link for every `composer_dir` it finds in the dataset. The default content handler of the DataLink Server will display a listing for the `classical lib` vertex that looks something like Figure 3-3. Clicking on one of the composers' names will take the user to the `composer` vertex where the DataLink Server will display something similar to Figure 3-3 with sections for `pieces`, `portrait` and `bio`. Observe how the `child` command is used to create these edges in the navigation graph by naming the next vertex a user could be able to get to from a given location.

At this point the reader may have noticed something queer about navigation

Current Path: [classical lib](#)

composer			
Antonio Vivaldi	Franz Schubert	George Gershwin	Gustav Mahler
Johannes Brahms	Ludwig Van Beethoven	Modest Mussorgsky	Wolfgang Amadaeus Mozart

Figure 3-3: Listing of the `classical lib` vertex

model and the output of the DataLink Server for the `classical lib` vertex. At no point in the navigation graph was the user given an option to choose the value of the `datasetName` attribute, which, according to the data model that was developed in Section 3.3.2, is necessary to resolve a path to the composer directories. Somehow the DataLink Server was able to produce results for the `composer` vertex anyway.

To understand how this happens recall the specification of the navigation layer’s interaction with the data layer. When the navigation layer requests a set of branches for a data vertex type, it is asking for all sets of attribute bindings which completely specify a data *and* are consistent with the set of attribute values determined by the current path through the navigation hierarchy. When the user first connects to the system at the `classical lib` vertex, no attribute values have been accumulated yet, so any set of attribute bindings that specifies a `composer_dir` will be returned by the data layer. The `datasetName` attribute has a value; it’s just been hidden from the user.

Now, suppose that the directory named `classical`, which houses the classical music dataset, shares a parent directory with another dataset, `punk_rock`. `punk_rock` is the home of another music library with roughly the same structure as the classical dataset. Inside `punk_rock` are some directories named after punk rock bands which are equivalent to composer directories in the classical dataset. Now when the user visits the `classical lib` vertex the DataLink Server will output a listing like the one shown in Figure 3-4.

Dead Kennedys et. al. are *not* the names of classical music composers. In the listing of Figure 3-4 the DataLink Server has branches for the “composer” directories from

Current Path: [classical lib](#)

composer			
Antonio Vivaldi	Franz Schubert	George Gershwin	Gustav Mahler
Johannes Brahms	Ludwig Van Beethoven	Modest Mussorgsky	Wolfgang Amadeus Mozart
Dead Kennedys	Generation X	Rancid	The Clash
The Exploited	The Ramones	The Sex Pistols	Warsaw

Figure 3-4: Another listing of the `classical lib` vertex

both datasets. The “classical” branches represent sets of attribute bindings that look like `{datasetName = "classical", composerName = "Johannes Brahms"}` and the “punk” branches have attribute binding sets such as `{datasetName = "punk_rock", composer = "The Clash"}`.

Usually this type of behavior is desirable. For example, if the name of the `composer lib` vertex was changed to `music lib` the output of Figure 3-4 would be appropriate. Suppose, however, that in this case we only want to make the classical library navigable.⁸ One way of doing this would be to change the signature of the `dataset` vertex type to `<signature>"classical"</signature>`. There are some cases, however, where the value of an attribute should be fixed for certain parts of the navigation hierarchy only. One example from the City dataset is a “show all rotated nodes” vertex, which would be the start of a navigation hierarchy for browsing only nodes that have completed the rotation post-processing phase. This new hierarchy would be in addition to the regular hierarchies for browsing the nodes in all post-processing stages and the way to implement it is with *properties*.

Attribute Values Can Be Fixed Using Properties

A property declaration has two arguments: the name of the attribute to set and the value to assign it. The following listing shows how to fix the value of the `datasetName`

⁸The music library is to be made available to the employees of the British Consulate, who’s administration does not share the same views of Queen Elizabeth as The Sex Pistols.

attribute using a property in the definition of the `classical lib` vertex:

```
<vertex name="classical lib">
  <child name="composer"/>
  <property name="datasetName" value="classical"/>
</vertex>
```

Properties can be set for any navigation vertex and there can be as many properties as there are attributes. Once properties are set they are inherited by all navigation vertices descending from the one in which the property was defined, so, for our example, the `composer`, `pieces`, `portrait` and `bio` vertices will only expand to branches in the classical library and not to their counterparts in the punk rock dataset.

Derived Properties are Used to Promote Attributes

So far, the navigation model we have scribed only describes the right-hand portion of the diagram in Figure 3-2 where the user follows the edge from the `classical-lib` vertex to the `composer` vertex and down to the music, image and biography files. This next code segment adds the left-hand path through the `opus number` vertex (comments have been included to indicate the changes):

```
<navModel>
  <vertex name="classical lib">
    <child name="composer"/>
  </vertex>
  <vertex name="composer" type="composer_dir">

    <child name="opus number"/> <!-- added this edge -->

    <child name="pieces"/>
    <child name="portrait"/>
    <child name="bio"/>
  </vertex>

  <!-- added this vertex: -->
  <vertex name="opus number">
    <child name="composer"/>
```

```

    <child name="pieces"/>
    <derivedProperty name="opusNum" source="mp3"/>
</vertex>

<vertex name="pieces" type="mp3"/>
<vertex name="portait" type="portait_img"/>
<vertex name="bio" type="bio_doc"/>

<root name="classical lib"/>
</navModel>

```

In this example the `<derivedProperty>` command has been used to promote the `opusNum` attribute to a higher level in the hierarchy. The branches displayed by the DataLink Server for the `opus number` vertex when viewed from the `classical lib` vertex will be the set of all unique opus numbers that exist in the dataset. The `source` argument of the `derivedProperty` tells the DataLink Server how to determine what the possible values of the derived property are. In this case the DataLink Server is instructed to do this by examining all of the `mp3` files that are consistent with the attribute values set by the user's current path through the navigation hierarchy. When the user is at the `classical lib` vertex, no attribute values have been accumulated, so the branches displayed for the `opus number` vertex are the opus numbers for every `mp3` file in the dataset. When the user is at the `composer` vertex, `composerName` has been bound to a value, so the set of opus number branches includes only the opus numbers of works by the selected composer.

Attribute Redirection

Attribute redirection can be used to reassign a named value to the name of an attribute for a particular vertex by using a `redirect` command in the body of a navigation vertex. The `redirect` command has the syntax:

```
<redirect source="name of source" destination="name of destination">
```

One example of where this is useful is a pair of special navigation vertices which bring up the baseline files for a particular node in the City dataset. Baseline files have a signature which looks like:

Parameter	Default Value
<code>supress_incomplete_leaves</code>	false
<code>merge_duplicates</code>	true
<code>enumerate_history</code>	true

Table 3.4: Default values of navigation vertex parameters

```
<signature>"%d_%d.trans", fromNode, toNode</signature>
```

Attribute redirection can be used to find the “to” baselines for the currently selected vertex. The “to” baselines are the baselines which point from the current node *to* another node (i.e the baselines for which `fromNode` is the currently selected node). To find the “to” baselines for the currently selected vertex, the City dataset employs a special navigation vertex, `to baselines` which has the definition:

```
<vertex name="to baselines" type="baseline_file">
  <redirect source="nodeId" destination="fromNode"/>
</vertex>
```

When the datalink server encounters this vertex, it assigns the value of `nodeId` (if any) to `fromNode`. A similar vertex is used to find the “from” baselines of a node.

Navigation Vertex Parameters

Navigation vertices have a small number of Boolean parameters which affect how they are handled by the DataLink Server. The names and the default values of these parameters are summarized in Table 3.4. The author of a navigation model can override the default values of these parameters for some vertices by including a `param` command in the body of the navigation vertex’s definition. The `param` command has the syntax:

```
<param name="parameter_name" value="true | false"/>
```

supress_incomplete_leaves The `supress_incomplete_leaves` parameter is relevant to the `opus number` navigation vertex that has just been added to the navigation model. As it stands now, when the user visits this vertex from the `classical lib` vertex, the DataLink Server will display branches for every composer in the dataset that has written a piece with the selected opus number as well as a set of branches for every audio file in the dataset with the selected opus number. This might be the behavior intended by the web architect. On the other hand, if the purpose of the `opus number` vertex was merely to reverse the order in which the user can select values for the opus number and composer name attributes then the DataLink Server shouldn't display audio files when the user is at the `opus number` vertex unless the user has arrived there from the `composer` vertex, and thus, has selected a value for the composer name attribute. To force the DataLink Server to take this second approach the `supress_incomplete_leaves` parameter should be set to **true** for the `opus number` vertex as follows:

```
<vertex name="opus number">
  <child name="composer"/>
  <child name="pieces"/>
  <derivedProperty name="opusNum" source="mp3"/>
  <param name="supress_incomplete_leaves" value="true"/>
</vertex>
```

When the `suppress_incomplete_leaves` parameter is set the DataLink Server will suppress the display of branches for leaf navigation vertices whose inherited attribute values have not been completely specified by the current navigation path. Therefore, with the `suppress_incomplete_leaves` parameter set, when the DataLink Server is at the `opus number` vertex it will not display branches for audio files unless it knows values for both the `datasetName` and `composerName` attributes.

merge_duplicates Sometimes the order of two attributes can be switched by some means other than a derived property. One example occurs in the City dataset for the attributes for image resolution and state of post-processing refinement. These

attributes derive their values from the names of directories in the City dataset. In the physical hierarchy of the City dataset the resolution directories are the parents of the post-processing directories. The navigation model for the City dataset allows the selection of these attributes to be reversed by cross-referencing the navigation vertices associated with them:

```
<navModel>
.
.
.
<vertex name="pose refinement" type="pose_refinement">
  <child name="resolution"/>
  .
  .
  .
</vertex>
<vertex name="resolution" type="resolution">
  <child name="pose refinement"/>
  .
  .
  .
</vertex>
.
.
.
</navModel>
```

In this case, when the user chooses a state of post-processing refinement first, the system should not behave as if a value for the refinement attribute has also been selected. The DataLink Server recognizes this case when it finds two branches with identical names but different sets of attribute bindings. For example, if the user made a selection for a state of post-processing refinement before choosing a node ID the system would find a whole bunch of branches named “half” for the image resolution attribute. The DataLink Server knows better than to provide selections for each of these branches. The DataLink Server would recognize that some of these like-named branches have different values for the node ID attribute, triggering the branch merging process which unifies all of the branches with similar names into one.

When two branches are merged, they are *generalized*. This means that all of the attribute bindings for attributes that were not set by the user via navigation which do not belong to the data vertex type (if any) of the navigation vertex of the branches are annulled. Thus, if the DataLink Server identified these two branches for the resolution vertex: `{nodeId = 0, refinement = "rotated", resolution = "half"}` and `{nodeId = 1, refinement = "rotated", resolution = "half"}` when the user had just made a selection for `refinement`, the DataLink Server would forward only one branch to the presentation layer. This branch would have the following set of generalized attribute bindings: `{refinement = "rotated", resolution = "half"}`.

The algorithm that performs branch merging and generalization is $O(n)$, where n is the number of branches before merging, so there is a small cost associated with merging when the number of branches is large. When it is known that duplicate branches can never occur for a particular navigation vertex, the `merge_duplicates` parameter can be set to **false** to disable the merging process for that vertex and improve the performance of the DataLink Server. The `node` vertex of the City dataset's navigation model is a good example of this because every node directory is identified by a unique ID number, and, therefore, there can never be duplicate branches for the `node` vertex.

enumerate_history In addition to the branches for each child of the selected vertex, the DataLink Server also returns sibling branches for all of the vertices in the history of the current navigation path. These can be formatted by using the `BranchHistoryScripter` tool in the DataLink Server API to create context menus which allow the user to jump back to earlier points in the navigation path, or to quickly make an alternate selection for a previously visited vertex. Enumeration for individual vertices can be turned off by setting the `enumerate_history` parameter to false. This can be used to reduce computation or to prevent the display of menus for vertices which may have a very large number of branches.

Formatting Rules for Branches and Branch Classes

The DataLink Server provides a couple of formatting options for branch names and branch class names. A branch class is the set of all branches belonging to a particular navigation vertex. In the default content handler view, the branch class name is used for the heading placed above the branch listing for a particular navigation vertex. As you can see from Figures 3-3 and 3-4, the default name for each branch class is simply the name of the corresponding navigation vertex.

A better branch class name can be provided for each navigation vertex by adding a `branchClassName` declaration to the body of the navigation vertex definition. There is a similar command, `branchName` which performs the same function for the names of branches. Any valid string format expression of the same form as a data vertex type signature expression can be used for a branch name or a branch class name.

The following code example shows how to improve the formatting of the `composer` vertex:

```
<modelDefs xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:no
NamespaceSchemaLocation="http://city.lcs.mit.edu:8080/data2/models/mode
ls.xsd">
  <dataModel>
    .
    .
    .
    <!-- composer directory: -->
    <vertexType name="composer_dir">
      <attributes>
        <string name="firstName"/>
        <string name="middleName"/>
        <string name="surname"/>
      </attributes>
      <signature>"%s %s %s", firstName, middleName, surname</signature>
      <signature>"%s %s", firstName, surname</signature>
    </vertexType>
    .
    .
    .
  </dataModel>
```

```

<navModel>
  .
  .
  .
  <vertex name="composer" type="composer_dir">
    <child name="opus number"/>
    <child name="pieces"/>
    <child name="portrait"/>
    <child name="bio"/>
    <branchName>"%s, %s", surname, firstName</branchName>
    <branchClassName>"Composers"</branchClassName>
  </vertex>
  .
  .
  .
</navModel>
</modelDefs>

```

Now the heading for composer branches will be “Composers” and each composer branch itself will have the form “Brahms, Johannes”. Notice that to do this some new attributes, `firstName`, `middleName` and `surname` had to be created, and the signature for the `compser_dir` had to be modified to extract the values for these attributes. In this listing I’ve only shown the changes relevant to this discussion on name formatting, but, clearly other vertices in the navigation and data models would have to be augmented with the new attributes, as well. The main thing to take away from this example, however, is how the two branch formatting commands, `branchName` and `branchClassName` are used.

Assigning Content Handlers to Navigation Vertices

To assign a custom content handler to a navigation vertex the `contentHandler` command is used. Here is an example of this command’s usage:

```

<vertex name="composer" type="composer_dir">
  <child name="opus number"/>
  <child name="pieces"/>
  <child name="portrait"/>

```

```
<child name="bio"/>
<branchName>"%s, %s", surname, firstName</branchName>
<branchClassName>"Composers"</branchClassName>
<contentHandler>/composer.jsp</contentHandler>
</vertex>
```

The `contentHandler` commands specifies a URL to the content handler for the vertex. This URL must begin with a forward slash, which specifies a URL relative to the home directory of the webapp where the DataLink Server is deployed.

3.5 Chapter Summary

That's pretty much all there is to the model file format. Now that you know how to use the XML-based modeling language to describe the organization of a physical dataset and the attributes of the data which should be navigable by writing a data model definition, as well as how to describe the navigable hierarchies the behavior of the navigation layer by defining a navigation model, you have mastered almost all you need to know to begin deploying powerful web interfaces to hierarchical datasets using the DataLink Server. The next skill to acquire is the ability to write content handlers to provide a clean, modular custom façade to the web interface provided by the DataLink Server. This will be the subject of the next chapter.

Chapter 4

Content Handlers

This chapter describes the API tools the DataLink Server package provides for writing content handlers. These tools include the `DataLinkDispatcher`, which allows a programmer to make requests to the `DataLinkServlet` for a particular branch or a resource with a given set of attribute values, and the `BranchHistoryScripter`, which allows a programmer to insert interactive menus to give the user some sense of the multidimensionality of the data space. This chapter also discusses the data structures which are used by content handlers and the `DataLinkServlet` to exchange information and describes the format of requests made to the `DataLinkServlet`.

4.1 Content Handlers Are JSPs, Servlets or HTML Documents

Dynamic content handlers can be constructed using Java Server Pages or Java servlets. In order to have access to the DataLink Server API, content handlers must reference the DataLink Server package by including the line:

```
import datalink.*;
```

This gives the content handlers access to the Java classes that are used to communicate with the `DataLinkServlet`, format branches and create context menus, as

well as the data structures for storing branches and branch classes. There are also some data structures for attributes and their values which are located in the package

`datlink.model.data.attribute`

There is no reason why HTML documents, or anything that can be referenced on the world-wide-web via a URL cannot be used for content handlers, but any components other than servlets and JSPs cannot access the Java-based DataLink Server API, so these alternative content handlers would only be able to display content that doesn't make use of any of the data forwarded by the `DataLinkServlet`.

4.2 The Format of DataLinkServlet Requests

Before we can begin discussing the interaction between content handlers and the `DataLinkServlet` it is important to make note of a few of the essential pieces of a `DataLinkServlet` request. Requests can be made to the `DataLinkServlet` using the GET or POST protocols. A request in the GET format has the general form outlined below:¹

```
http://city.lcs.mit.edu:8080/data2/DataLink?view=node&dataset=all-nodes  
-fixed&nodeId=75&history=dataset:all_nodes
```

The first parameter in this request URL, `view` specifies the name of the vertex to select. The `history` parameter specifies the list of vertices that have been visited along the current navigation path delimited by the `:` character, not including the currently selected vertex, which, in this case, is `node`. The rest of the parameters are the names and values of attributes.

The client can specify additional parameters in a DataLink Server request using the same `name=value` construct that is illustrated in this example. The DataLink

¹The name of the `DataLinkServlet` has been shortened in this URL to `DataLink` using a customization parameter of the webapp which deploys the DataLink Server. The reader unfamiliar with JSP and Java servlets might not know that the standard API for these tools allows the web author to create custom URLs for servlets and JSP deployed in a webapp, as has been done here for the `DataLinkServlet`.

Server treats any additional arguments to the request which do not correspond to attribute names as additional parameters for the content handler of the selected vertex and passes them on to the content handler, without interference.

The author of a content handler should never have to write a request like this by hand. The `DataLinkDispatcher` provides an API for formatting these request automatically, given an appropriate set of arguments, and this chapter shall not make a mention of the request format again, but before proceeding any further it is necessary for the reader to understand the operation of the `history` parameter because it is crucial in maintaining smooth navigation through the navigation hierarchies.

4.2.1 The history Parameter

The value of the history parameter is an ordered list of the navigation vertices that have been visited along the current navigation path. The primary reason that the DataLink Server needs to maintain a history is to ensure that a user can never visit the same navigation vertex twice along a single path through the navigation hierarchy when the navigation model contains cycles. Cycles are usually introduced into the navigation model by cross-references between navigation vertices which are used to make it possible for the user to invert the order in which a pair of attribute value

The function of the history is clearly a pretty important one, which might leave the reader asking why it is passed around as a parameter in `DataLinkServlet` request and not maintained somewhere in the internal state of the DataLink Server or in a Java Bean. The reason is that it is important for the DataLink Server to maintain a stateless architecture because it is implemented as a Java servlet. Well designed Java servlets should not maintain any state because the length of their lifecycle is not guaranteed. The servlet container can start and stop servlets at will, as long as they are not currently handling a request, in an effort maintain a good load balance on the host machine. This means that subsequent requests to the DataLink Server may be handled by different run-time instances of the `DataLinkServlet` class, and consequently, it is dangerous to try and maintain an internal state in the `DataLinkServlet`. For a similar reason, it is also not a good idea to maintain state information, like the

navigation history, within Java Beans.²

Another reason that the history is passed as an argument is that it serves as an implicit request for history enumeration, which can be used to make context navigation menus like the ones that are created by the `BranchHistoryScripter`. Section 4.5 in this chapter will expound the details of this use of the history further.

It is not necessary for the content handler developer to understand the format of the history parameter or how it is maintained, since this is the job of the `DataLinkDispatcher`. The developer of content handlers just needs to be aware of the history's purpose in order to understand when to use `DataLinkDispatcher` routines that invoke it and when it is safe to use the ones that do not.

4.3 Data Structures for Content Handlers

The chief purpose of content handles is to format the data served by the `DataLinkServlet` in a useful and pleasing way. Therefore, to write content handlers one needs to be familiar with the data structures that are used by the DataLink Server to encapsulate the data it communicates to them. This section outlines all of these important data structures briefly.

4.3.1 The `DataLinkServlet` Communicates to Content Handlers Using the `curPathBean`

All of the information about branches and navigation vertices that the `DataLinkServlet` provides for content handlers is communicated using a Java Bean called the `curPathBean`. The `DataLinkServlet` passes this bean to the content handler of a navigation vertex when that vertex is selected. This `curPathBean` is an instance of the `NavPathBean` class. This class has a number of routines for use in content handlers which can be used to obtain information about the current navigation path

²Any reference book on JSP and Java Servlet technology, such as *Professional JSP* [Brown et al., 2000], should be able to provide a more thorough treatment about the life cycles of servlets and Java Beans.

Method	Return Value
<code>getCurVtxAttrs()</code>	An <code>AttributeMapBean</code> containing the attributes bindings of the current navigation path
<code>getHistory()</code>	A <code>String[]</code> containing the current navigation history
<code>retrieveBranchClass("nav vertex")</code>	The <code>BranchClass</code> for "nav vertex"
<code>branchClasses()</code>	An <code>Iterator</code> containing the names of all the children of the selected vertex for which the <code>DataLinkServlet</code> has found branches

Table 4.1: `NavPathBean` routines for use in content handlers

and the available navigation options. Table 4.1 summarizes these methods. As you can see from Table 4.1, the `curPathBean` uses a number of additional data structures for encapsulating the information it holds about branches and attributes.

4.3.2 Data Structures for Attributes

Table 4.2 lists the three map classes that are useful in content handlers for storing sets of attribute name/value pairs. All of these maps have the same basic interface which includes a `get("name")` method for retrieving a named attribute value, and a number of `put("name", V)` methods for storing the value of an attribute. `NamedValueMap` and `SimpleNamedValue` map are essentially the same except that `SimpleNamedValueMap` has a simplified API that makes it compatible with Java 1.0. `SimpleNamedValueMap` is the storage class of choice for use in Java applets embedded in content handlers because its JDK 1.0 compatibility will ensure that the applet can run in older browsers.

The two named value map classes are utility classes for passing arguments to the `DataLinkDispatcher` to form requests to the DataLink Server. They should be used whenever the content handler needs to make a request using attribute values that were not provided as part of the current navigation path or a branch by the `DataLinkServlet`. If the navigation model for the dataset is designed properly, there should almost never be a need to do this in the body of a content handler because the

Map	Values Type	Usage
<code>AttributeMapBean</code>	<code>AttributeBean</code>	Used to store attributes bindings provided by the <code>DataLinkServlet</code>
<code>NamedValueMap</code>	<code>String</code>	Used to form custom queries (JDK 1.2)
<code>SimpleNamedValueMap</code>	<code>String</code>	Used to form custom queries (JDK 1.0)

Table 4.2: Map data structures for holding attribute sets

web architect can usually supply all of the data a content handler will need by making edges to the appropriate navigation vertices. The content handler can then access the data using the routines from the `DataLinkDispatcher` interface that can operate directly on the branches produced for these vertices. The two primary exceptions occur when the value of an attribute comes from a cache or when the request is made from within a Java applet, which cannot have direct access to the `curPathBean`.

The `AttributeMapBean` is the representation used by the `curPathBean` to store attribute bindings forwarded by the `DataLinkServlet`. Attributes are stored in an `AttributeMapBean` in bean form as instances of the `AttributeBean` class. This class has a very simple interface which includes a `getName()` and a `getValue` method. State attributes are stored as a subclass of `AttributeBean`, `StateAttributeBean`, which has an additional method, `getState()`, for retrieving the abstract state of a state attribute.

A Word About State Attribute Values

All of the map classes for storing attributes can work with attribute values represented as strings. Attributes values of any type can be represented as strings, but there are some special considerations for state attribute values in string form. Recall from Section 3.3.1 that state attributes can have an abstract state with no literal state or both an abstract state and a literal state. When a state attribute has a literal state, the string version of its value is simply the literal state it is in (i.e. “auto_rot”). When a state attribute has only an abstract state its string value is the name of the abstract state prefixed with a ! character, as in “!translated”. This reflects the way state

attributes values are passed in a query string to the `DataLink Server`. The `getValue()` method of the `StateAttributeBean` class will output string representations of state attribute values according to this convention.

4.3.3 Data Structures for Branches

The `DataLinkServlet` bundles all of the branches for a single navigation vertex into a `BranchClass` class. In addition to storing the branches themselves, a `BranchClass` stores some data which is shared by all of the branches in the class. This includes the name of the source navigation vertex and a flag which specifies whether the branches correspond to resources (physical files). Table 4.3 lists the methods of `BranchClass` which are of interest to authors of content handlers.

The branches themselves are represented by instances of the `Branch` class. The methods this class provides for getting at the data are given in Table 4.4. In an effort to reduce redundancy, the `DataLinkServlet` returns all of the attribute bindings of the current navigation path, which are shared by all of the branches, in the `curPathBean`. Only the attribute bindings which are specific to individual branches are stored in the branches themselves. Thus, the complete set of attributes for a given branch is a union of the current path's attributes and the attributes stored in the `Branch` class for that branch:

$$\text{curPathBean.getCurVtxAttrs()} \cup \text{branch.getAttributes()}$$

4.4 The `DataLinkDispatcher` Is Used to Format Requests to the `DataLink Server`

Now that the details of the data structures for storing attributes and branches have been articulated, the use of the `DataLinkDispatcher` can be investigated. The `DataLinkDispatcher` implements several different versions of these five methods for interfacing with the `DataLinkServlet`:

Method	Return Value
<code>getName()</code>	The name of this branch class, as specified in the navigation model
<code>getNavVtxName()</code>	The name of the navigation vertex corresponding to this branch class
<code>getBranches()</code>	A <code>Branch[]</code> of all of the branches in this class
<code>isResource()</code>	true if the branches are resources (leaf vertices); false if they are navigation vertices

Table 4.3: **BranchClass** routines for use in content handlers

Method	Return Value
<code>getBranchName()</code>	The formatted name of this branch, as specified in the navigation model
<code>getAttributes()</code>	An <code>AttributeMapBean</code> containing the attribute bindings of this branch
<code>getLastModified()</code>	The timestamp of the branch in milliseconds, if the branch is for a navigation vertex that is associated with a data type; -1 if the source vertex is purely navigational
<code>getSize()</code>	If this branch is associated with a physical datum, this method returns its size in bytes; it returns 0 if the associated navigation vertex is purely navigational

Table 4.4: **Branch** methods for content handlers

Method	Return Value
<code>getDataLinkServer()</code>	Returns a string containing the URL to the DataLink Server
<code>formatHistoryPath(String[] pHistory)</code>	Formats the navigation history into a path-like string delimited by / characters
<code>sortBranches(Branch[] pBranches)</code>	Sorts a branch array lexicographically by name

Table 4.5: Other useful methods provided by the `DataLinkDispatcher`

1. `formatViewRequest(...)`
2. `formatViewResourceRequest(...)`
3. `formatViewRequestURL(...)`
4. `formatViewResourceRequestURL(...)`
5. `openResourceStream(...)`

All of these methods are essentially the same in their operation, in that they are used to make requests to the DataLink Server given a branch or a set of attributes and, possibly, a history. Some other methods implemented by the `DataLinkDispatcher` which may be useful for content handlers are summarized in Table 4.5.

The `formatViewRequest` and `formatResourceRequest` methods return a string containing a GET protocol request, such as the one from Section 4.2. These methods are useful for creating request URLs for making hyperlinks to branches or passing data to embedded applets. `formatViewRequestURL` and `formatViewResourceRequestURL` do the same thing only they output their results in a Java URL class. `openResourceStream` is capable of making the same requests as the above methods, except that it opens an `InputStream` directly to the resource, which can be used to open files for reading and parsing.

There are several different versions of each of these request formatting methods, each of which takes a different combination of arguments. Some versions operate directly on instances of the `Branch` class and data from the `curPathBean`. Others

enable the programmer to use the attribute map data structures from Section 4.3.2 to make requests using an arbitrary set of attribute bindings. To go into the details of each of these variations would be overly fastidious. However, the interested reader can examine the exhaustive listing of the methods in the `DataLinkDispater` API that is located in Appendix A.

4.4.1 View Requests vs. View Resource Requests

In and of itself, the `formatViewRequest` method provides all of the functionality needed to make requests to the DataLink Server. The other methods exist primarily for convenience and simply incorporate a few other tasks that are commonly associated with making requests to the DataLink Server, such as opening an input stream. The `formatViewResourceRequest` and `formatViewResourceRequestURL` methods are somewhat special, however.

When the DataLink Server returns the resource branches corresponding to a leaf vertex in the navigation graph, it has already done all of the work it will ever need to do to retrieve the resources associated with these branches; it already had to find them once to determine whether they exist and what their attributes are. The attributes associated with each branch are enough to *completely* specify its location, so to find the resource associated with one of these branches all the DataLink Server has to do is ask the data layer to resolve the physical location for the resource directly from the attribute bindings; no interaction with the navigation layer is necessary. When the request is made with the standard view request format, however, the DataLink Server has no way of knowing that it is retrieving a resource without invoking a query to the navigation layer.

View resource requests include an extra parameter which tells the DataLink Server that it is ok to resolve the attribute bindings directly to a resource.³ This makes requests for physical data, which can often occur in large numbers, quite a bit more efficient. It is a good practice to use view resource requests whenever possible in

³If you remember Figure 2-1 from the chapter on the architecture of the DataLink Server, this invokes the data path labeled “Path 2”.

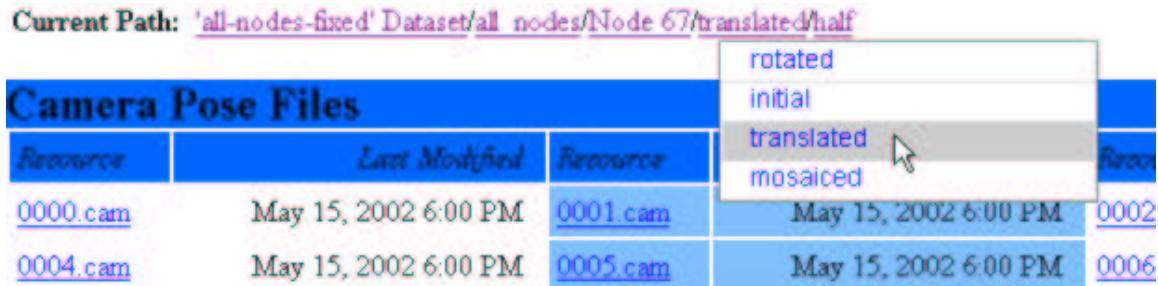

Figure 4-1: Screen shot of a navigation context menu

content handlers. It is always possible to determine whether a branch corresponds to a resource by calling the `Branch` class' `isResource()` method. One caveat that is important to keep in mind, however, is that view resource requests made with abstract state values instead of literal state values will evaluate to garbage, because it is necessary to invoke the data matching process in order to resolve abstract states to literal states. This is only a concern when making requests to the DataLink Server for data that does not correspond to one of the branches in the `curPathBean` because all state attributes in these branches are completely specified with both abstract and literal states.

4.5 Making Menus With the BranchHistoryScripter

By now the reader has gotten a sense of how things that are always in the same place in the fixed data hierarchy can be swapped and moved around in the navigation hierarchy, where they may be reachable by more than one path. This makes navigation much more flexible and universal, but without some kind of context information to guide the user, it can be hard for them to develop a mental model of the data space. The `BranchHistoryScripter` can be used in content handlers to generate navigation context menus that serve as both powerful navigation interfaces and virtual sign posts for the user which help to assuage this difficulty. Figure 4-1 shows one of these navigation context menus in action.

As Figure 4-1 shows, the menus that the `BranchHistoryScripter` produces take the form of a / delimited path constructed from the names of the branches that the

user has traversed. Mousing over one of these branch names brings up a pop-up menu which lists all of the other options the user could have chosen in addition to the selection that they did make. Selecting on of these options will take the user back to that branch in the navigation hierarchy. In Figure 4-1 the user has activated the menu for the pose refinement selection vertex.

As was mentioned in Section 3.4.1, it is possible for the author of a navigation model to suppress history enumeration. When enumeration is suppressed, the `DataLinkServlet` will not include a complete listing of sibling branches for implicated navigation vertex. Consequently, when the `BranchHistoryScripter` generates a context menu for a suppressed vertex, it only provides the user with two options. One of these takes the user back to the branch they selected. The other is labeled “choose another”, and returns the user to the selected branch of the parent of the suppressed vertex. Thus, if the user activated the context menu for the node vertex in Figure 4-1, for which enumeration is suppressed, the only two options that it would present would be “Node 67”, the currently selected branch, and “choose another”. Selecting “choose another” would take the user back to the “all nodes” navigation vertex, where the user would again be presented with a set of nodes to browse.

The Context Menus Use Javascript and DHTML

Javascript is the medium of choice for creating the navigation context menus because it is “low-tech” enough to be compatible with most browsers, unlike Flash and Java⁴, and, more importantly, it is lightweight enough to avoid compromising the performance of the presentation layer. The `BranchHistoryScripter` provides two methods which are used to generate the Javascript which creates these menus at runtime in DHTML (hence the name “Scripter”).⁵ The first of these, `insertMenusScript`,

⁴Although I have used Java extensively throughout the City Data web portal I have steered away from the Java Swing components that would be necessary to make pop-up menus, which are only supported in version 1.2 implementations of the Java Runtime Environment. Netscape and Microsoft have been lackadaisical in supporting this technology, and, consequently, it is only now beginning to appear in the newest browsers.

⁵I used an off-the-shelf, open-source implementation of the Javascript menus created by Gary Smith of the Netscape corporation. The source code and documentation of Smith’s Javascript menu

generates the Javascript that sets up and creates the menu objects. It should be used to place this code somewhere between the header and the body of the document that is output by the content handler. For example:

```
<HTML>
  <HEAD>
    <TITLE>The MIT City Scanning Project Dataset</TITLE>
  </HEAD>

  <% String strBGColor = "FFFFFF", strHeadingColor = "0066ff", strColC
olor = "7ebffc"; %>

  <jsp:useBean id="curPathBean" scope="request" type="NavPathBean"/>

  <% int n, j;
    Branch[] pBranches;
    BranchClass[] pBranchHistory = curPathBean.getBranchHistory();
    String[] pHistory = curPathBean.getHistory();
    AttributeMapBean curVtxAttrsBean = curPathBean.getCurVtxAttrs();
  %>

  <%-- Create the Javascript menu objects: --%>

  <% BranchHistoryScripter.insertMenusScript(new PrintWriter(out), curP
athBean); %>

  <BODY BGCOLOR="<%= strBGColor %>">
  .
  .
  .
```

As the example shows, the `BranchHistoryScripter` gets all of the information it needs directly from the `curPathBean`. In addition to the `curPathBean`, the programmer only has to provide the method with a writer to the output stream of the request response that is being issued by the content handler.⁶ The content handler writer

object are available from `<http://developer.netscape.com/viewsource/smith_menu/smith_menu.html>`. Javascript is a tricky thing to make compatible with all of the different web browsers that are out there, which is why it is a good idea, as well as a time-saving practice, to use something that is tried-and-true.

⁶This is JSP-speak for the document that is output by the content handler JSP or servlet.

can now insert the navigation context menus anywhere in the body of the document using the `insertBranchHistory` method:

```
.
.
.
<BODY BGCOLOR="<%= strBGColor %>">

    <CENTER><H2>The MIT City Scanning Project Dataset</H2></CENTER>

    <!-- Insert the navigation context menus here: --%>

    <P><% BranchHistoryScripter.insertBranchHistory(new PrintWriter(ou
t), curPathBean); %>
.
.
.
```

4.6 Chapter Summary

Having read this chapter, the reader should now have acquired the knowledge necessary to begin developing content handlers for a web interface created using the DataLink Server. This provides a flexible and modular way of creating a useful and aesthetically pleasing front end to a web interface defined using the modeling language of Chapter 3. This chapter, in conjunction with the previous chapter on modeling data and navigation using XML, should provide the foundation necessary for a developer to begin using the DataLink Server. The next chapter will focus on how the DataLink Server system actually works. For a more in-depth summary of the `DataLinkDispatcher` API, be sure to check out Appendix A.

Chapter 5

Operation of the DataLink Server

This Chapter will describe how the core of the DataLink Server system works. It will describe the algorithms and data structures used by the `DataLinkServlet` to service requests to the DataLink Server. This will include a discussion of the `DataModel` and the `NavModel`, the software implementations of the data layer and the navigation layer, and will conclude with a walkthrough of a view request and a view resource request.

5.1 Data Structures for Curbing Computational Complexity

As has been discussed in Chapter 2, the software components that implement the data layer and the navigation layer are the `DataModel` and the `NavModel`. By now, the reader should be aware that the basic structure of these classes is a directed graph. This section will expound the workings of these graph structures a little further.

One of the major items of concern in designing the DataLink Server was controlling the computational complexity of the algorithms it employs for exploring the navigation graphs and locating data. Finding specific vertices in each of the graphs is something that the the models have to do several times for every request that is serviced by the `DataLinkServlet`, and, as the number of levels in either the data or

navigation hierarchies increases, so do the number of lookups grow, in an exponential fashion. This means that brute force search through the models is not an option because these individual searches, themselves, would be inherently slow; searching through a network really amounts to searching through a tree, and the fastest time anyone can hope to do that in is $O(b^d)$, where b is the branching factor of the graph and d is the depth¹ (in this case, the number of levels in the hierarchy) [Korf, 1988].

Fortunately, the fact that the DataLink Server searches for vertices which are guaranteed to have unique names means that it can do a lot better if the graphs are each backed by a hash table which allows the DataLink Server to lookup a vertex by name, in constant ($O(1)$) time. Both the `DataModel` and the `NavModel` employ this strategy. In each of these structures the vertices are represented by atomic vertex objects, each of which maintains an array of pointers to its children. The models can locate a vertex object in the hash table, using the name of the vertex as a key. Then, to explore the vertex’s children (or ancestry, in the case of the `DataModel`) the model simply has to follow the pointers stored in each vertex to walk the edges of the graph like a linked list. In the case of the `DataModel`, hash table lookup is also used to locate `DataVertexType` objects, which hold the signatures and attribute definitions of individual data types.

Hash functions are exploited throughout the DataLink Server’s implementation to speed up algorithms. This is crucial in many places, because the number of branches and attributes under consideration balloons rapidly. The following sections will illustrate a number of these tricks.

5.2 DataLink Server Requests Come in Two Flavors

Section 4.2 gave a glimpse of the format of DataLink Server requests. This section will explain them in detail. There are two types of DataLink Server requests, *view*

¹One can do a little better bidirectional search, which has the time requirement, $O(2b^{d/2}) \sim O(b^{d/2})$, at an increased cost in spacial requirements [Korf, 1988].

requests and *view resource* requests.

5.2.1 View Requests

View requests ask the DataLink Server to retrieve the branches for all of the children of a navigation vertex (if any), that are consistent with a particular set of attribute bindings, and display the content handler of the selected vertex. The content handler for a vertex which corresponds to a resource is the resource itself. View requests have the following format:

```
http://city.lcs.mit.edu:8080/data2/DataLink?view=node&dataset=all-nodes  
-fixed&nodeId=75&history=dataset:all_nodes
```

In this example, the URL to the `DataLinkServlet` is given by:

```
http://city.lcs.mit.edu:8080/data2/DataLink
```

The name of the `DataLinkServlet` has been shortened to “DataLink” in this example. It is possible, using configuration parameters of the webapp which deploys the DataLink Server, to re-map the URL to the `DataLinkServlet` to anything that is convenient.

As Section 4.2 indicated, the `view` parameter of the DataLink Server request specifies the name of the next navigation vertex to display. That happens to be the `node` vertex, in this example. The `history` parameter is a `:` delimited list of the navigation vertices visited thus far along the current navigation path. The vertices visited are listed, in order, from left to right, beginning with the first vertex visited on the left. As was mentioned in Section 4.2.1, the history is passed in the DataLink Server request in order to maintain a stateless architecture for the `DataLinkServlet`. When necessary, it is the joint responsibility of the `DataLinkServlet` and content handlers to ensure the the history is updated properly. When it is not relevant, the history parameter can be omitted from view requests.

The rest of the parameters of this DataLink Server request example are attribute bindings. In this case, the request specifies that the value of the `dataset` attribute

should be “all-nodes-fixed” and the value of the `nodeId` attribute should be 75. This request is asking the DataLink Server to return all of the branches for each of the children of the `node` vertex which are consistent with the set of attribute bindings: `{dataset = "all-nodes-fixed", nodeId = 75}`.

The client can specify additional parameters in a DataLink Server request using the same `name=value` construct that is illustrated in this example. The DataLink Server treats any additional arguments to the request which do not correspond to attribute names as additional parameters for the content handler of the selected vertex and passes them on to the content handler, without interference.

5.2.2 View Resource Requests

View resource requests ask the DataLink Server to serve a physical resource, without invoking a query to the navigation layer. In order to do this, the attributes supplied in the request must completely specify the resource to retrieve. History parameters and additional parameters have no effect on view resource requests and are simply ignored by the DataLink Server. The following is an example of a view resource request:

```
http://city.lcs.mit.edu:8080/data2/DataLink?view=sphere&resource=SPHERE
&nodeId=45&dataset=all-nodes-fixed&sphere_res=64&res=half
```

As the example shows, a view resource request is specified by adding an additional parameter, `resource` to what would otherwise be a view request. The value of this parameter should be the name of the data vertex which corresponds to the resource to retrieve (when the DataLink Server returns branches that correspond to physical resources, it includes this information in the `curPathBean` for use by the `DataLinkDispatcher`).

5.2.3 Specifying Abstract State Values

When making a request to the DataLink Server it is often necessary to make requests with state attribute values given as abstract states. After all, the whole idea of

the DataLink Server is to abstract away the hierarchy of the physical data, so the navigation and presentation layers should not have to know the literal state values of state attributes are.

To specify the value of a state attribute as an abstract state instead of a literal state, the attribute binding in the request should take the form of this example: `refinement=!initial`. Here, `!initial` is the name of the “initial” abstract state of the `pose_refinement` attribute, prefixed with a `!` character to indicate that the value is an abstract state instead of a literal state. To specify a literal state, the client lists the attribute binding with the name of the literal state, omitting the `!` prefix.

5.3 How the DataLink Server Handles View Requests

The best way to describe how the DataLink Server handles a view request is to walk through one step by step. This section will do just that, beginning with what the DataLink Server does as soon as it receives a request. It may help to have a visual reference to accompany this discussion, so the data paths diagram from Chapter 2 is repeated here in Figure 5-1 for convenience.

The first thing the DataLink Server does when it receives any request is to parse the request and determine what type it is. To determine the request type, the DataLink Server looks for the presence of the `resource` parameter. If this parameter is not included in the request, the DataLink Server treats the request as view request and proceeds by extracting the selected navigation vertex v_N from the `view` parameter. It then bundles up the set of attribute bindings, B_{in} , supplied by the request into a `NamedValueMap` for programmatic access by the `NavModel` (the attributes are later translated into DataLink Server’s native, internal representation when more information about what data types they are to be associated with is known). Finally, the DataLink Server parses the history, if one was supplied with the request, into a convenient form and makes a *select vertex* request to the navigation layer with all of

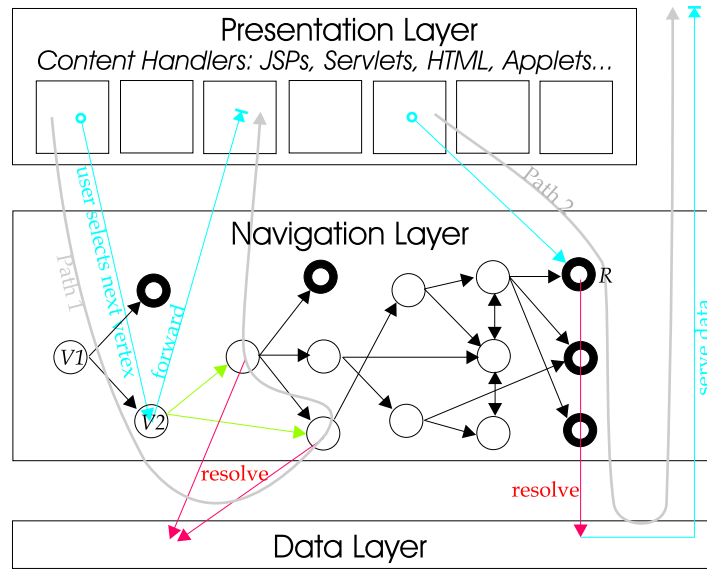

Figure 5-1: Data paths through the DataLink Server

this information.

5.3.1 How the Navigation Layer Handles a Select Vertex Request

Recall that the software implementation of the navigation layer is the `NavModel` class. When this class receives a select vertex request, it must examine navigation graph to see whether the selected vertex, v_N , is an interior vertex or a leaf vertex. This determines whether the DataLink Server should take “Path 1” or “Path 2”. If the answer is “Path 1”, the `NavModel` will have to make requests to the `DataModel` for the branches of each of the children of v_N . If it is “Path 2”, the `NavModel` will have to ask the `DataModel` to resolve the path to the appropriate resource and serve it to the client. Here is an enumeration of the steps the `NavModel` takes in this process:

1. If v_N has any properties associated with it, named value pairs for each of these are added to B_{in} . If any of the properties are in conflict with attribute bindings in B_{in} , these attribute bindings are replaced by the property values.

2. If there are any attributes in B_{in} which are redirected by v_N , these attributes are renamed at this time.
3. If v_N is a leaf vertex, the **NavModel** makes a request to the **DataModel** to resolve the path to the corresponding resource, given the attribute bindings in B_{in} , and serve the data to the client. Otherwise, the **NavModel** proceeds to Step 4
4. Loop over each of the children of v_N :
 - 4.1 Get the next child, c , of v_N .
 - 4.2 Check to see whether c is in the history. If it is, skip c and go back to Step 4 to get the next child vertex.
 - 4.3 Create a duplicate of B_{in} , B_c .
 - 4.4 Check whether c is associated with a data vertex type, T . If so, jump ahead to Step 4.5. Otherwise c is a *purely navigational* vertex.
 - 4.4.1 If there are no derived properties associated with c , add a single branch named after c with the attribute bindings, B_c , to the **curPathBean** and go back to Step 4 to process the next child.
 - 4.4.2 Otherwise, promote the attribute, a_p , associated with c 's derived property by adding a null-valued binding for a_p to B_c and setting a flag, *bDerivedProp*, which indicates that all branches for c with the same value for a_p should be merged and generalized. Set T to the source data vertex type of the derived property.
 - 4.5 If c has any properties, insert them in B_c , overriding any conflicting attribute bindings.
 - 4.6 If c redirects any attributes, rename the appropriate bindings in B_c .
 - 4.7 Make a request to the **DataModel** for all of the sets of attribute bindings which map to data of type T and are consistent with B_c .
 - 4.8 Unless the **merge_duplicates** flag is set to **false** for this vertex, check to see if c is not a leaf vertex or if the flag *bDerivedProp* is set, and, if

either of these conditions is true, merge and generalize all of the duplicate branches returned by the `DataModel` (if any).

- 4.9 Add the branches (if any) to the `curPathBean` and loop.
5. If the `suppress_incomplete_leaves` flag is set for v_N then remove any branches from the `curPathBean` for leaf vertices with which are not completely specified by the bindings in B_{in} .
6. Append v_N to the history.
7. Forward the `curPathBean` to the content handler for v_N .

This is a lot of steps, to be sure, but most of them are pretty straightforward. One part of this process which is worth discussing before delving into the details of how the `DataModel` handles its part of the transaction, however, is the branch merging and generalization operation that is performed in Step 4.8.

Hashing Makes Merging More Efficient

If the `NavModel` did a straightforward, item by item comparison of each of the branches of c to check for duplicates, the time requirement for this process would be $O(n^2)$, where n is the number of branches. This could be a serious bottleneck because n can often be very large. This can be reduced to an $O(n)$ problem, however, by applying a hash function to each of the branches in order to create a hashed set. Whenever two branches are the same, they will always generate the same hash code, and if the hash function is a good one, then, most of the time, when branches are different they will generate different ones. Thus, the `NavModel` can merge the branches quickly by placing each one in the hashed set, and watching for hash code collisions. Whenever there is one, the `NavModel` compares the two branches, and if they are indeed the same, merges and generalizes them.

Branches are compared by name, and the hash function that is used to place them in the hashed set is the standard Java hash function for strings:²

²The hash code for null strings is defined to be 0.

$$H_{string} = 31^{n-1}s_0 + 31^{n-2}s_1 + \dots + s_{n-1} \quad (5.1)$$

In order to reuse this hash function for merging branches based on the value of a derived property, the value of the property is compared in string form. This eliminates the need to use a different hashing strategy for each of the different attribute types.

5.3.2 How the Data Layer Fetches the Branches for a Data Type

In Step 4.7 of the navigation layer's procedure for handling a select vertex request, it requests all of the branches for the data type, T , of one of the selected vertex's children, given a set of attribute bindings B_c , from the data layer. Here are the steps that the data layer takes to procure these branches:

1. The **DataModel** looks in its table of data vertex definitions for all of the instances of type T and finds their locations in the graph by hashing.
2. For each of the instances, $v_{D_{head}}$, of type T that the data layer finds, It follows the edges in the data model graph to build an ancestor chain from $v_{D_{head}}$ to a root vertex, $v_{D_{tail}}$, in the data graph.
3. For each chain, i , the data layer then adds any unresolved attributes of i to the set of attribute bindings, B_c , to create a new set of attributes, A_i (some of which may be null-valued, and some which may not), which will be used to match the request to physical data.
4. Finally, the data layer accumulates all of the possible bindings for each of the A_i and returns them all, bundled as branches in a **BranchClass**, to the navigation layer.

How the Data Layer Matches Attributes to Physical Data

Step 4 is the part of this procedure where the data layer matches partial sets of attribute bindings to physical data specified by a data vertex chain. This is done using a very simple recursive procedure applied to each vertex chain. In addition to a vertex chain and the corresponding attribute set, A , the matching procedure also takes as arguments a base path and a start index, i , into the vertex chain. Before making the entry-level call to this procedure, the data layer initializes the base path to be the root path to the dataset and sets $i = index(v_{D_{tail}})$. Here is an outline of this procedure:

1. Loop over each vertex in the chain starting at v_i and terminate at $v_{D_{head}}$:
 - 1.1 Try to evaluate the signature for v_i using the bindings in A . If successful, append the evaluated signature to the base path, decrement i , and go back to Step 1 to process the next vertex. Otherwise, proceed to the next step (signature evaluation will fail if required attributes are null):
 - 1.2 Obtain a listing of all of the files and directories at the location specified by the base path.
 - 1.3 For each datum in the listing, attempt to bind the null-valued bindings of v_i to the attributes of the datum. If successful, create a new attribute set A_i by inserting the new bindings into A and call this procedure again with $i = i - 1$, A_i and a new base path constructed from the evaluated signature of v_i appended to the old base path, and add the results to a vector of bindings, $V_{bindings}$.
 - 1.4 Return the bindings in $V_{bindings}$.
2. **Base case:** Once the head vertex is reached, obtain a listing of all of the data located at the base path.
3. For each datum in the listing, attempt to bind the null-valued bindings of v_i to the attributes of the datum. If successful, create a new attribute set A_i by inserting the new bindings into A and add it to the vector of bindings, $V_{bindings}$.

4. If A contains any state attributes that are specified by *abstract state* only, examine the A_i to see if any pair of them is *equivalent*. If so, *unify* the implicated pair.
5. Return $V_{bindings}$.

Attribute Set Equivalence and Unification When the client makes a request using abstract state values for state attributes, it doesn't care what the literal state of the data is, as long as it is the *most preferred* state when there are more than one options available.³ When the data layer uncovers two sets of bindings which are the same except for the literal states of a pair (or pairs) of state attributes, the two sets of attribute bindings are *equivalent*. The data layer should only return the set with the preferred literal state, whose value should be annulled.

To do this, the data layer must, in Step 4, compare each of the A_i for equivalence. This is reminiscent of the merging procedure discussed earlier, in Section 5.3.1. In this case the problem is exacerbated by the fact that, in order to check for equivalence, each pair of corresponding attributes in a pair of attribute sets must be compared, but the hashing step can still be used to help if a new hashing function is defined for attribute sets. The hash code for an attribute set, A , containing attribute bindings $a_0, a_1 \dots a_N$, that is used in this implementation of the DataLink Server is defined to be:⁴

$$H_A = \sum_i^N H_{string}(name(a_i))^{H_{string}(value_S(a_i))} \quad (5.2)$$

Here, the function $value_S(a_i)$ returns the string value of a_i ; in the case of state attributes $value_S(a_i)$ returns the *abstract* string value. H_{string} is the same hash function as that used for branch merging (Eq. 5.1). The hash function for attribute sets is designed so that if two sets contain the same key/value pairs, they will always have the same hash code, regardless of the order of the attributes in the sets. In this case

³Recall from Section 3.3.1 that the preferential ordering of literal states is given by the sequence in which their signatures appear in the state attribute's definition in the model file.

⁴The hash code of the empty attribute set is defined to be 0.

equivalent, but not necessary equal attribute sets will always have the same hash code as well, because the hash code used for state attributes is the hash code of their abstract state. This is exactly the behavior that is needed in this case, because it will always trigger a comparison when attribute sets are equivalent, but avoid needless comparisons most of the the times when they are not. Using this hash function to place the attribute sets in a hashed set is a quick and dirty, linear time way of checking for equivalent attribute sets.

5.4 How the DataLink Server Handles View Resource Requests

View resource requests are considerably simpler for the DataLink Server to process. The influence of the navigation layer is minimally invasive, because the view resource request explicitly specifies a data vertex and there are no children to explore. The navigation layer simply requests that the data layer resolve the physical path to the data using the supplied attributes. The data layer can do this without invoking the matching and binding process described in Section 5.3.2, because the implicit assumption of a view resource request is that the resource is completely specified by the supplied attributes (If, for some reason, when trying to evaluate the physical path, the data layer finds that a necessary attribute was not supplied it reports an error and returns nothing). In fact, aside from retrieving the ancestor chain for the request data vertex, the extent of the data model's involvement corresponds to carrying out the same process it uses for accumulating the base path (Steps 1 and 1.1 of the matching algorithm), except that instead of terminating at the head vertex, it evaluates its signature as well.

For clarity, here is an explicit enumeration of these steps:

1. Initialize the base path to be the root path of the dataset.
2. Loop over each vertex in the chain for the requested data vertex.⁵

⁵Remember that I mentioned that data vertices are currently only allowed to have one parent

- 2.1 Evaluate the signature for the current vertex and append it to the base path.
3. Serve the data at the accumulated path.

in Chapter 3, and hence, here, they can have only one chain. Adding support for multiple parents would require some modification to the view resource request because the attribute bindings, by themselves, might be ambiguous.

Chapter 6

The Geospatial Coordinate Transformation Library

The second major contribution of this thesis, in addition to the DataLink Server, is the Geospatial Coordinate Transformation Library. This coordinate transformation library was conceived out of a desire to unify data in the City Scanning Dataset, which is represented in the City group’s internal coordinate system, with the vast amount of geospatial data, such as maps and satellite images, that exists in the world—but it grew into a much broader vision: to encapsulate all of the most commonly used geospatial coordinate transformations into one, powerful, customizable and comprehensible library which can be reused in any software application.

The Geospatial Coordinate Transformation Library (GCTL) supports transformations between the four most commonly used representations of points on the Earth’s surface: geographic coordinates, which are expressed in latitude and longitude; geocentric coordinates, which are used by satellites and GPS systems; cartographic coordinates, which are used in maps; and local grid coordinates, which are often used for surveying. Prior to the existence of this library, there were no static libraries that programmers could use to perform all of these tasks together. This is a major grievance, because transformations between three or more different geospatial representations may often need to be done in tandem. One extreme example occurred in the City Scanning Project, when over the past year, the team developed an inter-

est in exchanging information between the City dataset’s geospatial images of MIT’s campus and a campus base map, maintained by the Department of Facilities. This requires transformations which span all four of the geospatial coordinate domains and is now accomplished by GCTL.

6.1 Problems With Existing Packages

In order to appreciate some of the advantages of the software design principles that went into the interface of GCTL, it is worthwhile to take a look at some of the problems with existing packages that motivated them. Aside from the lack of a single unified API for geospatial coordinate transformations there are several other deficiencies associated with the other, pre-existing coordinate transformation packages:¹

1. **There is a dearth of programmatically accessible coordinate transformation libraries.** Most of the pre-existing tools are packaged as software applications which offer the developer no way to access them from within program code. The closest many of these packages come, is the ability to read coordinates from a text file, or other source, and output them in another format, but there is no standard input format and the user’s source data is usually not in the correct one to begin with.
2. **Those packages which exist in library form are difficult to use without a solid foundation in geodesy² and geospatial coordinate transformation.** The problem with many of these platforms is that the coordinate frames of reference are implicit. Therefore it is difficult for inexperienced user’s to figure out exactly how to chain multiple transformations together.

¹There is such a large assortment of geospatial coordinate transformation packages and applications that it is too intractable to list them all here. A few of the most useful ones are: Proj.4 [Warmerdam, 2000], [Evenden, 1995a], [Evenden, 1995b], [Evenden, 1995c] and NADCON [National Geodetic Survey, 2002a], which is part of a large collection of free tools, the Geodetic Toolkit [National Geodetic Survey, 2002b], provided by the National Geodetic Survey.

²Geodesy is the science of the Earth’s shape (which is not as trivial as you may think) and models for expressing coordinates on its surface.

3. **Poor usage of non-object-oriented models is pervasive throughout these tools.** A lot of the transformation APIs available stick to basic C implementations in an effort to make them simple, portable and generic. This turns out to be a pain more than a panacea, however, because the typical API, under this model, consists of a single, general initialization routine, that sets up an individual transformation, and another solitary, generic transformation routine. This is problematic because it necessitates the use of global static variables, forcing the programmer to reinitialize the transformation methods every time they want to switch transforms. Almost all coordinate transforms require so many static parameters that is much better from an architectural point of view to encapsulate the transforms in powerful classes tailored to specific coordinate frames.³

6.2 GCTL Makes Reference Frames Explicit

In addition to being a universal coordinate transformation tool, the design of GCTL's API is geared to tackling problems 2 and 3, as well. Consider the following example for projecting latitude and longitude coordinates to US State Plane Coordinates in the Massachusetts mainland zone, using the Proj.4 library [Warmerdam, 2000], which is typical of most publicly-available coordinate transformation APIs:

```
pParams[0] = new char[12];
pParams[1] = new char[16];

//Initialize a State Plane projection for Mass. mainland (zone 2001):
pParams[0] = "units=us-ft";
pParams[1] = "init=nad27:2001";

PJ *pStatePlaneProj;

if(!(pStatePlaneProj = pj_init(sizeof(pParams)/sizeof(char *), pParams))
```

³I'm not taking sides on an OOP vs. no-OOP debate, here; I'm just making an observation about an example where OOP is better suited to the problem.

```

    fprintf(stderr, "Couldn't initialize state plane projection.");

projUV uv;

uv.u = 73;
uv.v = 65;

uv = pj_fwd(uv, pStatePlaneProj);

printf("x = %f, y = %f", uv.u, uv.v);

```

This is not egregious, but it's not superb, either. There's no need to spend time lambasting it, but a couple of observations about this sample will demonstrate the advantages of GCTL:

- The generic initialization function necessitates an awkward calling convention. More importantly, however, without precise arguments, there is no way a programmer can even begin to setup this transformation without diving into the documentation.
- There is no way to tell which one of `uv.u` and `uv.v` is latitude and which is longitude.
- The universal coordinate data type, `uv`, which is both the input and output of `pj_fwd`, makes it impossible to tell what type of coordinates the data is really expressed in.
- If the call to `pj_fwd` was isolated from the initialization and output code, as it is likely to be in a real program, it would be impossible to infer whether `pj_fwd` is transforming *to* or *from* state plane coordinates.

Now, consider the same transform implemented using GCTL:

```

//Initialize a State Plane projection for Mass. mainland (zone 2001):
StatePlaneProjector spProj(2001);

LLA lla = new LLA(65, 73, 0);

```

```
USSP sp = spProj.project(LLA);

printf("x = %f, y = %f", sp[0], sp[1]);
```

The odious Proj.4 code has metamorphosed into into something in which the programmer always knows what type of coordinates are in use and what type of arguments are appropriate for each transformation. For a more provocative example, investigate the following piece of code, which is used to transform a point in Cartesian coordinates, expressed in the NAD83 datum, to a point in State Plane coordinates:

```
lla = NAD83Datum.XYZtoLLA(v3NAD83);
lla = nadConv.NAD83toNAD27(lla);
sp = spProj.project(lla);
```

Without knowing something about geospatial coordinate systems (as you may not, just yet), it's hard to understand the purpose of each of these steps. For example, you wouldn't know that State Plane coordinates are expressed relative to the NAD27 datum (whatever that is), so, before the State Plane projection can be applied to the coordinates, they must be shifted from the NAD83 datum in which they are currently expressed, to NAD27. What is clear in this example, however, is that, in the first step, some Cartesian coordinate expressed relative to some frame of reference named NAD83 is being transformed to an LLA coordinate, also expressed relative to NAD83. Then, in step two, the reference frame of the LLA coordinate is shifted from NAD83 to NAD27. Finally, the coordinate is projected to state plane coordinates.

6.2.1 Design Principles of GCTL

The examples in the previous section illustrate several of the software design principles that went into the GCTL API. Briefly, these are:

- Though it may require learning more classes and methods, it is better to create simple classes which are designed to do one specific task well, than to try to pack too much power into a generic portal.

- Associate each transform with a frame of reference.
- Use a naming convention the specifies to and from coordinate types explicitly
- Coordinate types should have their own data types

Some of the advantages of embracing these conventions are:

- The system is easy to learn because of the teleological naming convention.
- The library is extensible; to add new transforms, all one has to do is extend one of the simple base classes or create a new one. There is no need to modify, or understand the implementation of, the existing API.
- All of the tools associated with a particular coordinate system or frame of reference are localized to one computation structure tailored for that task. This, in turn, facilitates chaining multiple transformations.

6.3 GCTL Understands Five Types of Coordinates

Before describing how to perform geospatial coordinate transformations with GCTL, it is worth reviewing the types of of geospatial coordinate systems GCTL can work with. GCTL knows about six different types of coordinate systems, whose definitions follow:

Geodetic Coordinate Systems are geospatial coordinates expressed in terms of latitude, longitude and altitude, with respect to a specific model of the Earth called a *datum*.

Geocentric Coordinate Systems are geospatial coordinates expressed with respect to a set of Cartesian coordinate axes. The origin of the geocentric coordinate axes is the center of the ellipsoidal approximation of the Earth's shape that is used by the particular datum in which the geocentric coordinates are expressed.

Earth-Centered, Earth Fixed (ECEF) Coordinates is a special name for geocentric coordinates expressed relative to the WGS84 datum.

Local Grid Coordinates are Cartesian coordinates associated with an arbitrary set of coordinate axes. Typically, the coordinate axes are defined in terms of a **local tangent plane** (LTP) system.

Local Tangent Plane coordinate systems consist of a right-handed set of coordinate axes with the z axis normal to the Earth's surface and the x and y coordinate axes lying in a plane tangential to the Earth, where the x axis points East and the y axis points North.⁴

Cartographic Coordinate Systems are 2D projections of geospatial coordinates that are used in maps.

Unless otherwise noted, geocentric, ECEF and local grid coordinates are all expressed in units of meters. Different cartographic coordinate systems may use US feet, meters or other units.

6.3.1 Datums are Models of the Earth's Surface

Over time, as the science of geodesy has progressed, people have come up with more and more accurate models of the Earth's surface. Often these can be used anywhere on the Earth, but sometimes they are only meant to be used in specific regions of the globe. These models are called *datums* and consist of an ellipsoidal model of the Earth's surface which is centered at the at the origin of some Cartesian coordinate system.⁵ The origin of these axes *may* be located at the true center of the Earth, for datums that are meant to be accurate anywhere on the planet, or it might be located some distance away, in the case of datums which are dedicated to a specific region.

⁴This type of coordinate system is also sometimes referred to as an East North Up (ENU) or East North Height (ENH) coordinate system [Hofman-Wellenhof et al., 1997].

⁵In geodesy, almost all models of the Earth's shape are ellipsoidal. This is only an approximation (the actual shape of the Earth is something more like a distended pear), but it is reasonably accurate and makes the mathematics behind geospatial coordinate transformations tractable.

Datum	Reference Ellipsoid	GCTL Class
generic datum	-	GeoDatum
NAD27	Clark 1866	NAD27_Datum
NAD83	GRS80	NAD83_Datum
WGS84	WGS84 Ellipsoid	WGS84_Datum

Table 6.1: GCTL Datum Classes

The WGS84 datum, which is used by GPS systems and is accurate anywhere on Earth, uses an ellipsoid which is almost exactly the same size as the Earth and is also concentric with it. The NAD27 datum, on the other hand, is slightly smaller than the Earth is and is localized at a point such that it is tangential to the Earth’s surface at Mead’s Ranch in Kansas. Consequently, it is only accurate in North America [Hofman-Wellenhof et al., 1997].

Geodetic and geocentric coordinates are always defined with respect to a datum. You may previously thought that latitude and longitude coordinates were universal, but in actuality, since they are dependent on the Earth’s shape, which is approximated by using some reference ellipsoid, they are correlated with a datum. Geocentric coordinates are the same way. They are defined with respect to a Cartesian coordinate system originating from the center of a reference ellipsoid, which can be defined precisely, mathematically—not with respect to the Earth’s true center, which is only known approximately. For this reason, it is not possible to transform geodetic or geocentric coordinates to any other coordinate system, unless the datum in which they are expressed is known. This is the reason why GCTL contains constructs such as:

```
lla = NAD83Datum.XYZtoLLA(v3NAD83);
```

This statement converts geocentric coordinates to geodetic coordinates, where both coordinate systems are expressed relative to the NAD83 Datum. GCTL also contains mechanisms for performing shifts between datums. The datums which GCTL knows about are listed in Table 6.1. Datums usually employ one of many named ellipsoids. GCTL also has internal representations of these, which are listed in Table 6.2.

Ellipsoid	GCTL Class
generic ellipsoid	Ellipsoid
Airy 1830	Airy1830_Ellipsoid
Australian National	Australian_National_Ellipsoid
Bessel (for Ehiopia, Indonesia, Japan and Korea)	Bessel1841_BR_Ellipsoid
Bessel (for Namibia)	Bessel1841_BN_Ellipsoid
Clarke 1866	Clarke1866_Ellipsoid
Clarke 1880	Clarke1880_Ellipsoid
EE (W. Malaysia and Singapore, 1948)	EE_Ellipsoid
ED (W. malaysia, 1969)	ED_Ellipsoid
Everest	Everest_Ellipsoid
GRS80	GRS80_Ellipsoid
Helmert 1906	Helmert906_Ellipsoid
Hough 1960	Hough1960_Ellipsoid
India 1830	India1830_Ellipsoid
India 1956	India1956_Ellipsoid
International 1924	International1924_Ellipsoid
Krassovsky 1940	Krassovsky1940_Ellipsoid
Modified Fisher 1960	Modified_Fischer1960_Ellipsoid
South American 1969	South_American1969_Ellipsoid
WGS72	WGS72_Ellipsoid
WGS84	WGS84_Ellipsoid

Table 6.2: GCTL Ellipsoid Classes

New datums classes for use with GCTL can be created by extending the generic `GeoDatum` base class as follows:

```
class New_Datum : public GeoDatum
{
public:
    New_Datum() : GeoDatum(Some_Ellipsoid()
                           , deltaX, deltaY, deltaZ
                           , rotX,   rotY,   rotZ
                           , scale) {};
};
```

Here, the additional arguments after the ellipsoid are the elements of a 4×4 homogenous matrix which defines the change of basis from the new datum to WGS84⁶

⁶WGS84 is the common datum that GCTL uses to link all datums together.

(As Section 6.4.4 will describe, GCTL performs datum shifts by performing a change of basis on geocentric coordinates). This matrix has the form:

$$\begin{bmatrix} \sigma & r_z & -r_y & \Delta X \\ -r_z & \sigma & r_x & \Delta Y \\ r_y & -r_x & \sigma & \Delta Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (6.1)$$

ΔX , ΔY and ΔZ are the translational offsets from center of the new datum's ellipsoid to the origin of WGS84 and correspond to `deltaX`, `deltaY` and `deltaZ`, respectively. The `scale` parameter specifies σ , the scaling factor for changing units between the two datums. The last three parameters, `rotX`, `rotY` and `rotZ` correspond to r_x , r_y and r_z , respectively. These parameters describe the rotation between the new datum's axes and WGS84's. These parameters are a fairly standard way of defining datum shifts and can usually be looked up in a table, somewhere, such as [EUROCONTROL and IfEN, 1998].

To define a new ellipsoid for use in GCTL, one can derive a new ellipsoid class from the generic `Ellipsoid` class as follows:

```
class New_Ellipsoid : public Ellipsoid
{
public:
    New_Ellipsoid : Ellipsoid(majorAxis, flattening) {};
};
```

In this example, `majorAxis` is the semi-major axis of the ellipsoid. `flattening` is the *geometric flattening*, which is a special parameter that is commonly used to describe geodetic ellipsoids, and is defined by:

$$f = \frac{a - b}{a} \quad (6.2)$$

where a is the length of the semi-major axis of the ellipsoid and b is the length of the semi-minor axis [Hofman-Wellenhof et al., 1997].

6.4 Using GCTL

In this section the reader will learn about the GCTL API. This will include an overview of the basic data types and an exposition of the all of the different types of transformations which can be carried out using GCTL. This section will illuminate as much as the reader should need to know about geospatial coordinate systems to understand the basics of GCTL, its implementation and it's usage.

6.4.1 GCTL Data Types

There are two data main structures for representing coordinates in use in GCTL: `Vector3D` and `LLA`. `Vector3D` is used for any 3D Cartesian coordinate system, which includes geocentric and local grid coordinates. Cartographic projections each have their own special data types. For example US State Plane coordinates are represented by a `USSP` data type. The data types for cartographic projections are really just `typedefed Vector3D` classes with names that evoke the coordinate system they represent. For cartographic coordinates, the third component of the underlying `Vector3D` type is implicitly 0.⁷

An `LLA` is used to store coordinates as latitude, longitude and altitude. Coordinates of this form are called *geodedic* coordinates. They may also sometimes be referred to as a latitude, longitude, height (LLH) coordinates. The precise definition of altitude varies with the coordinate systems and surveying methods in use, but for all of the coordinate systems used in GCTL, altitude refers to the perpendicular distance of a point from the surface of a reference ellipsoid.⁸

GCTL performs computations only on `LLA` coordinates expressed in radians. This is usually not the format that the source data is in, or the one that the programmer

⁷In keeping with the conventions of Section 6.2.1 it would seem like a good idea to define a `Vector2D` data type for cartographic projections. I considered this, but decided to stick with `Vector3D` because it facilitates matters when cartographic projections need to be thought of as planar projections in three-space. One real example of this is when the City group extrudes building façades from a campus basemap in cartographic coordinates to check against the 3D geometry of the City Data images.

⁸Some alternate representations of altitude are based on isoclines in the earth's gravitational field [EUROCONTROL and IfEN, 1998].

wants to use in the output, so the LLA class has two methods for switching back and forth between radians and degrees. Each of these outputs a new LLA object, with the value of the original expressed in the alternate angle format:

1. LLA `toDeg()` `const`;
2. LLA `toRad()` `const`;

6.4.2 Defining Local Grid Coordinate Systems

ECEF coordinates are the “common language” which GCTL uses to connect most of the coordinate systems it can work with together. Every coordinate system object in GCTL, except for the cartographic projections, has methods for converting to and from ECEF coordinates (or WGS84 geocentric coordinates, which are the same thing). Therefore, to hook up a custom coordinate system to the GCTL library, all one has to know is the change of basis transformation from the local coordinates to ECEF. If this transformation is not known it can be established using GPS surveying techniques, as described in [Hofman-Wellenhof et al., 1997] or aerophotometry [EUROCONTROL and IfEN, 1998]. Once the change of basis is established, it can be written down in homogenous matrix form and used to initialize a `LocalGridCoordSys` object in GCTL, as in the following example, which creates a transformation object for for the City Group’s LTP coordinate system:⁹

```
Mat44 m44CityLTP(0.94603, -0.21836, 0.23944, 1529571.69879,
                 0.32406, 0.63746, -0.69901, -4465216.36854,
                 0,      0.73888, 0.67383, 4275544.15726,
                 0,      0,      0,      1);

LocalGridCoordSys cityLTP(m44CityLTP);
```

Once a local grid coordinate system has been created, the `LocalGridCoordSys` class provides two methods for converting local grid coordinates to ECEF coordinates and back:

⁹The matrix elements in this example are only shown to five significant digits to save space. The real City LTP coordinate system is defined with much greater precision.

1. `Vector3D LGCtoECEF(const Vector3D &v3) const;`
2. `Vector3D ECEFtoLGC(const Vector3D &v3) const;`

6.4.3 GCTL Can Convert Between Geodetic and Geocentric Coordinates

Converting between geodetic and geocentric coordinates of the same datum can be done with an instance of one of the datum classes derived from the `GeoDatum` base class. This class provides two method for converting between geodetic and geocentric coordinates: `LLAtoXYZ`, for converting geodetic to geocentric coordinates, and `XYZtoLLA` for converting geocentric to geodetic. The prototypes for these methods are:

1. `Vector3D LLAtoXYZ(const LLA &LLA) const;`
2. `LLA XYZtoLLA(const Vector3D &v3) const;`

The source code for GCTL's implementation of geocentric/geodetic conversions is located in Appendix C. What follows, is a terse, mathematical summary of the steps involved. It makes use of some additional ellipsoid constants which can be computed from the reference ellipsoid's semi-major axis, a , semi-minor axis, b , and geometric flattening (Eq. 6.2):¹⁰

$$e^2 = f(2 - f) \tag{6.3}$$

$$e'^2 = \frac{a^2 - b^2}{b^2} \tag{6.4}$$

The procedure GCTL uses for computing geocentric coordinates from geodetic coordinates, where ϕ = latitude, θ = longitude and h = altitude, is:

¹⁰Eq. 6.3 is the eccentricity of the ellipsoid squared.

1. $\theta' = \begin{cases} \theta & \theta < \pi \\ \theta - 2\pi & \theta \geq \pi \end{cases}$ Change the range of longitude to be $-\pi$ to π .
2. $R = \frac{a}{\sqrt{1-e^2 \sin^2 \phi}}$ Compute Earth's radius at the specified point.
3. $x = (R + h) \cos \phi \cos \theta'$ Compute x .
4. $y = (R + h) \cos \phi \sin \theta'$ Compute y .
5. $z = (R(1 - e^2) + h) \sin \phi$ Compute z .

Toms' Method For Converting Geocentric to Geodetic Coordinates

There is no closed form formula for converting from geocentric to geodetic coordinates; all existing methods for performing this transformation are approximations. The method for transforming between geodetic and geocentric coordinates that was used to implement the geocentric to geodetic transformation in the `GeoDatum` class is the Toms method [Toms, 1996]. Toms' method is relatively new, and it hasn't appeared in much of the literature yet. The most common method currently in use is Helmert's formula [EUROCONTROL and IfEN, 1998] (which exists in both an iterative and an analytic form), but this method is much less accurate than Toms'. In testing on the City dataset and a few other data sources, both versions of Helmert's transformation were only able to produce results to within a few meters accuracy.¹¹ Toms' method, on the other hand, was able to produce results with centimeter accuracy on the same data. It takes the following steps:

1. $R_z = \sqrt{x^2 + y^2}$ Compute the distance from the z axis.
2. $v_0 = Kz$ Estimate distance of $(\phi, \theta, 0)$ from the equatorial plane.
3. $h_0 = \sqrt{v_0^2 + R_z^2}$ Estimate radius of $(\phi, \theta, 0)$.
4. $v_1 = z + be'^2(\frac{v_0}{h_0})^3$ Revise estimate of v_0 .
5. $S = R_z - ae^2(\frac{R_z}{h_0})^3$ Estimate the radius of $(\phi, \theta, 0)$ projected onto the equatorial plane.

¹¹Theoretically, Helmert's method can produce results with centimeter accuracy, but small errors in the source data tend to blow up fairly quickly, especially when the ellipsoid parameters for the reference datum are imprecise.

$$\begin{array}{ll}
6. \ h_1 = \sqrt{v_1^2 + S^2} & \text{Revise estimate of } h_0. \\
7. \ \sin \phi = \frac{v_1}{h_1} & \text{Compute sin of latitude.} \\
8. \ \cos \phi = \frac{S}{h_1} & \text{Compute cos of latitude.} \\
9. \ R = \frac{a}{\sqrt{1-e^2 \sin^2 \phi}} & \text{Compute Earth's radius at the specified point.} \\
10. \ \phi = \begin{cases} \frac{\pi}{2} & x = 0, y \neq 0, z \geq 0 \\ -\frac{\pi}{2} & x = 0, y \neq 0, z < 0 \\ \tan^{-1} \frac{\sin \phi}{\cos \phi} & o.w. \end{cases} & \text{Compute latitude.} \\
11. \ \theta = \begin{cases} \frac{\pi}{2} & x = 0, y > 0 \\ -\frac{\pi}{2} & x = 0, y < 0 \\ 0 & x = 0, y = 0 \\ \tan^{-1} \frac{y}{x} & o.w. \end{cases} & \text{Compute longitude.} \\
12. \ h = \begin{cases} \frac{R_z}{\cos \phi - R} & \cos \phi \geq L \\ -\frac{R_z}{\cos \phi - R} & \cos \phi \leq L \\ \frac{y}{\sin \phi} + R(e^2 - 1) & o.w. \end{cases} & \text{Compute altitude.}
\end{array}$$

This makes use of two constants that Toms defines: $K = 1.0026000$ and L , which is the cosine of 67.5 degrees. The conditionals in steps 10 and 11 are to check for special cases, when the point is at the equator or the poles. In the actual implementation, these are checked earlier in a trivial rejection step. For a better understanding of why this method works, please see [Toms, 1996].

6.4.4 GCTL Can Do Datum Shifts

The XYZtoLLA and LLA to XYZ methods provide a way to switch back and forth between geodetic and geocentric coordinates in the same datum, but sometimes it is also necessary to shift between two different datums, especially when preparing to do a cartographic projection, as some of these are only defined for certain datums. Performing a datum shift on LLA coordinates directly is hard, but it can be done using the Molodensky approximation or multiple regression equations [EUROCONTROL and IfEN, 1998]. A simpler method can be derived, however, by making the observation that when coordinates in two different datums are expressed

geocentrically, the only difference between the two datums is the position and orientation their coordinate axes, relative to each other. Thus, performing a datum shift on geocentric coordinates is essentially a change of basis, which can be done by applying a homogenous matrix, such as Eq. 6.1 to the geocentric coordinate vectors. GCTL's datum classes have two methods for doing this:

1. `Vector3D toWGS84(const Vector3D &v3) const;`
2. `Vector3D fromWGS84(const Vector3D &v3) const;`

Thus, to change from NAD83 to WGS84, using an instance of the `NAD83_Datum` class, `NAD83Datum`, one would apply function 1 like this:¹²

```
Vector3D v3ECEF = NAD83Datum.toWGS84(v3NAD83);
```

To transform between two arbitrary datums using GCTL, one first converts geocentric coordinates from the first datum to WGS84. Then, to get coordinates in the second datum, one transforms the intermediate results from WGS84 to the second datum. To reduce computation by doing this all in one step, one can compose the “to WGS84” matrix of the first datum with the “from WGS84” change of basis matrix of the second. These matrices are defined in GCTL using a `Mat44` (Matrix 4×4) class, which has functions for matrix multiplication operations, so it is easy to do this.

Grid Shifts Are Used to Deal With Older Datums

Many datums, such as the North American Datum of 1927 (NAD27) were surveyed using conventional techniques, before the advent of satellites and GPS. This poses a problem because many of these datums are still in use today, but the inaccuracies in their measurements are the cause of non-linearities in shifts between the older datums and newer ones. As Figure 6-1 shows, these non-linearities between the datums can be quite significant.¹³

¹²In reality, no one ever performs the shift between these two particular datums because they are almost identical. There is, generally, a much larger difference between other pairs of datums, however.

¹³This data was obtained from the National Geodetic Survey , [National Geodetic Survey, 2002a].

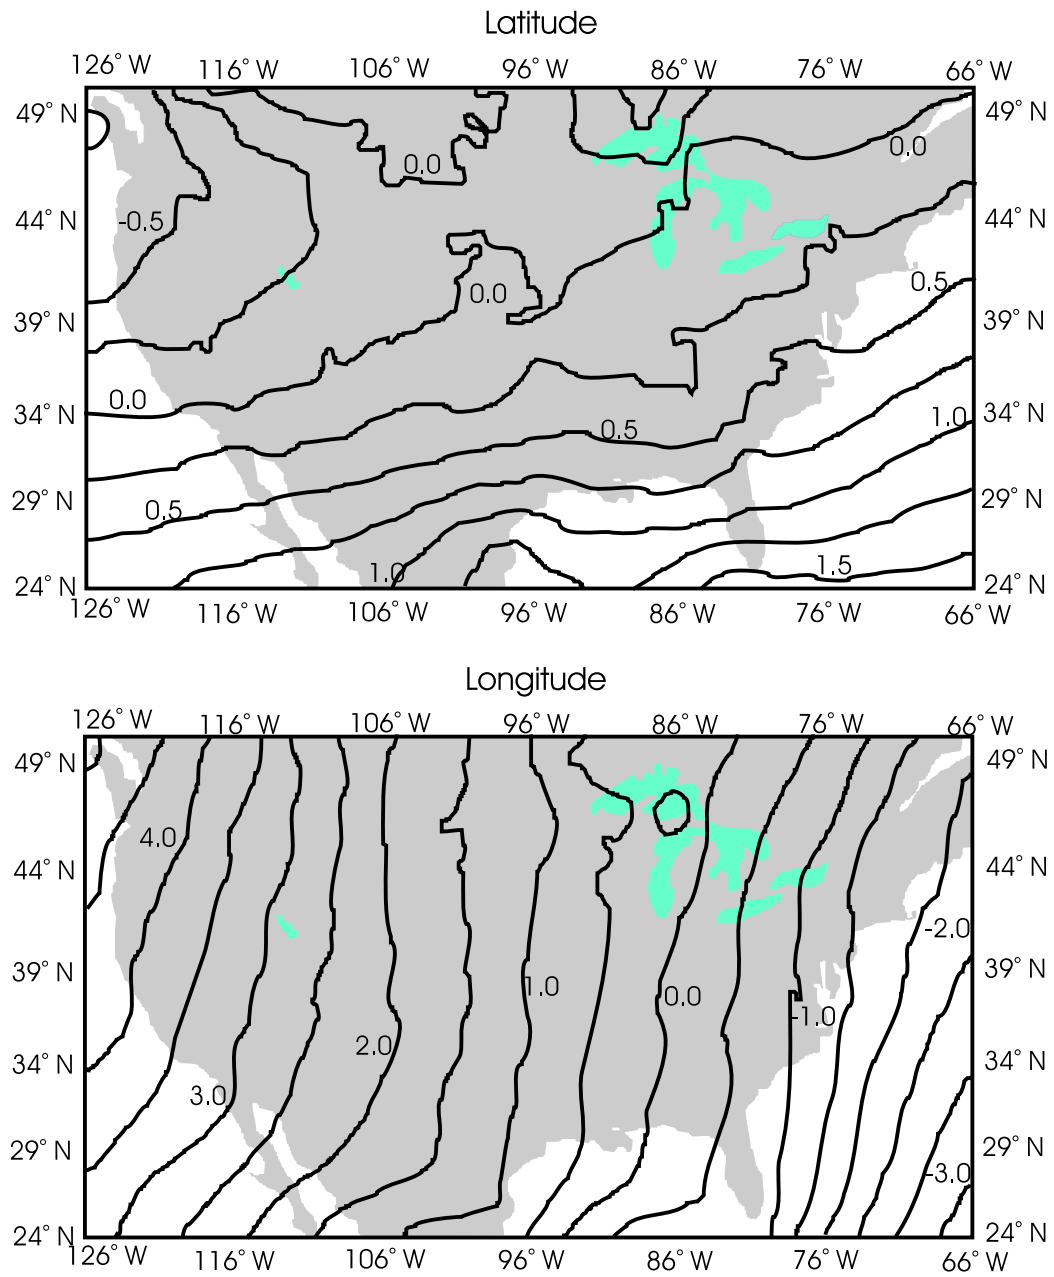

Figure 6-1: NAD83 - NAD27 datum shifts in arc seconds

This problem was of particular interest to the City group because we wanted to unify the City dataset with a base map of campus that is encoded in US State Plane coordinates, which are a cartographic projection in the NAD27 datum. Fortunately, the National Geodetic Survey has done some work in establishing some grids of very precise control points in both the NAD27 and NAD83 Datums. Accurate datum conversions between NAD27 and NAD83 for individual points can be obtained by linearly interpolating between nearby grid points, in what is known as the NADCON method [National Geodetic Survey, 2002a].

GCTL has a class which implements this conversion called `NADConv`. This class has two methods for converting between NAD28 and NAD83 geodetic coordinates:

1. `LLA NAD27toNAD83(const LLA &lla);`
2. `LLA NAD83toNAD27(const LLA &lla);`

In order to use these methods, one must create an instance of the `NADConv` class, initialized with the grid for the geographic region of interest. This is done using the `NADConv loadGrid` function:

```
//load the grid file for continental US:
if(!nadConv.loadGrid(CONT_US))
    fprintf(stderr, "Couldn't load continental US grid file: %s"
            , nadConv.getLastErr());
```

As the example shows, GCTL has a `#defined` moniker for each of the grid files. These are listed in Table 6.3. The example also demonstrates the use of the `NADConv` class' error reporting mechanism, the function `getLastErr()`, which produces a string containing a description of the last error encountered. Errors can arise either in loading the grid file, or when converting coordinates if the converted coordinate lies outside of the specified grid region. When this happens, the value returned by `NAD83toNAD27` or `NAD27toNAD83` will be `(HUGE_VAL, HUGE_VAL, h)`, where `HUGE_VAL` is the value of infinity defined in the standard C math library.

Table 6.3: GCTL NADCON Grids

6.4.5 GCTL Can Make Maps With Cartographic Projections

GCTL also has the capability to perform cartographic projections. It does this by building a friendly interface to the Proj.4 cartographic projections library. Though, somewhat denigrated for its clumsy interface earlier in this chapter, Proj.4's virtue is the over 100 cartographic projections it supports. There are too many of these to list here, but the Proj.4 documentation provides a complete description of them [Warmerdam, 2000].

Carrying out cartographic projections with Proj.4 the same type of interface that should be familiar with by now. Each cartographic projection class in the Geospatial Coordinate Transformation Library descends from a common base class called **MapProjector**. Each of the different map projector implementations may require slightly different initialization parameters, if any, which are usually some type of indication of the geographical region of interest or the units in which to output the results, but once created they all share the same method for performing projections:

```
Vector3D project(const LLA &lla) const;
```

The output of any cartographic projection is two-dimensional, so the z value of the vector returned will always be zero (as I mentioned earlier, the reason that the output is placed in a 3D Vector is to facilitate the use of the projection data in 3D applications). Also, as stated in Section 6.4.1 the sub-classes of **MapProjector**

that implement individual transforms have their own `typedefed` monikers for the `Vector3D` output of the `project` function.

The `MapProjector` class also provides a routine for doing inverse cartographic projections:

```
LLA toLLA(const Vector3D &v3Proj) const;
```

The results returned by this method will always have a zero altitude, however, since there is no height information stored in the 2D cartographic coordinates. This does not, however, result in a loss of accuracy in the other two dimensions.

6.5 Chapter Summary

Upon finishing this chapter, the reader should have a pretty good idea of GCTL's capabilities, as well as how to extend them. While mastery of the intricacies of geospatial coordinate transformation comes with practice, this chapter has provided the principle details that the reader should need to get started. One of the many benefits of GCTL extolled in this text is the way that it makes coordinate types and reference frames explicit. It is my hope that this dramatically accelerates the learning curve of any users who begin incorporating this transformation library in their own programs.

Chapter 7

Advanced Features of the Extended Web Interface

The addition of the new navigation/data retrieval infrastructure provided by the DataLink Server and the geospatial coordinate transformations afforded by GCTL have made possible a wealth of new features for the extended web interface to the City Scanning Project Dataset. This chapter serves as a showcase of this new technology, in which I will describe a number of extensions to the visualization tools in the web interface. I'll also document a number of tools which will be useful in the continued development of this project and make some suggestions about powerful additional features that can now be added with ease by taking advantage of the new tools I have created.

7.1 Enhanced Visualizations

The visualization tools for the pre-existing web interface have been re-equipped with some new advanced features. This section will describe a few of them.

7.1.1 Extensions to the Map Viewer

The development of the Geospatial Coordinate Transformation Library has made it possible to re-implement the Map Viewer using a vector format map, instead of a crude raster graphic. This map is derived from a CAD format base map of MIT's campus which is maintained by the MIT Department of Facilities, and is expressed in US State Plane coordinates. Using GCTL this map has been exported to the City Group's LTP coordinate system, and, for the first time, the world has a view of how accurately the City group's geospatial imagery is registered with respect to an outside data source. The new Map Viewer provides the most accurate depiction of where the nodes in the City dataset are located on campus.

Figure 7-1 shows a screen shot of the new Map Viewer with the nodes overlaid on the vector format map. The numbers displayed in the status window of this screen shot are the coordinates of the mouse's location within the Map Viewer window expressed in the City LTP system.

One advantage of using a vector format map is that it makes it possible to zoom in without aliasing problems. Using the new map viewer, the user can now specify a viewing region by dragging out a rectangle on the screen with the mouse. This allows the viewer to get a close up view of buildings, sidewalks and other structures to see where the nodes lie in relation to objects in the physical world. The user can then examine the accompanying view from the node's eye in the Mosaic Viewer to see how items on the map look from the node's point of view. Right clicking zooms back out again, and if the legend ever gets in the way it can be dragged and dropped to a new location.

Figure 7-2 shows the Map Viewer zoomed in to get a closer view of the nodes in the courtyard around the Green Building (building 54). Notice that the Map Viewer is pretty smart about zooming. No matter how elongated a rectangle the user draws, it maintains the proper aspect ratio in the zoomed in view (the zoom is scaled to fit the largest dimension of the rectangle that the user draws). Also, the Map Viewer automatically numbers nodes when the view is zoomed in enough that labeling the

Figure 7-1: The new Map Viewer

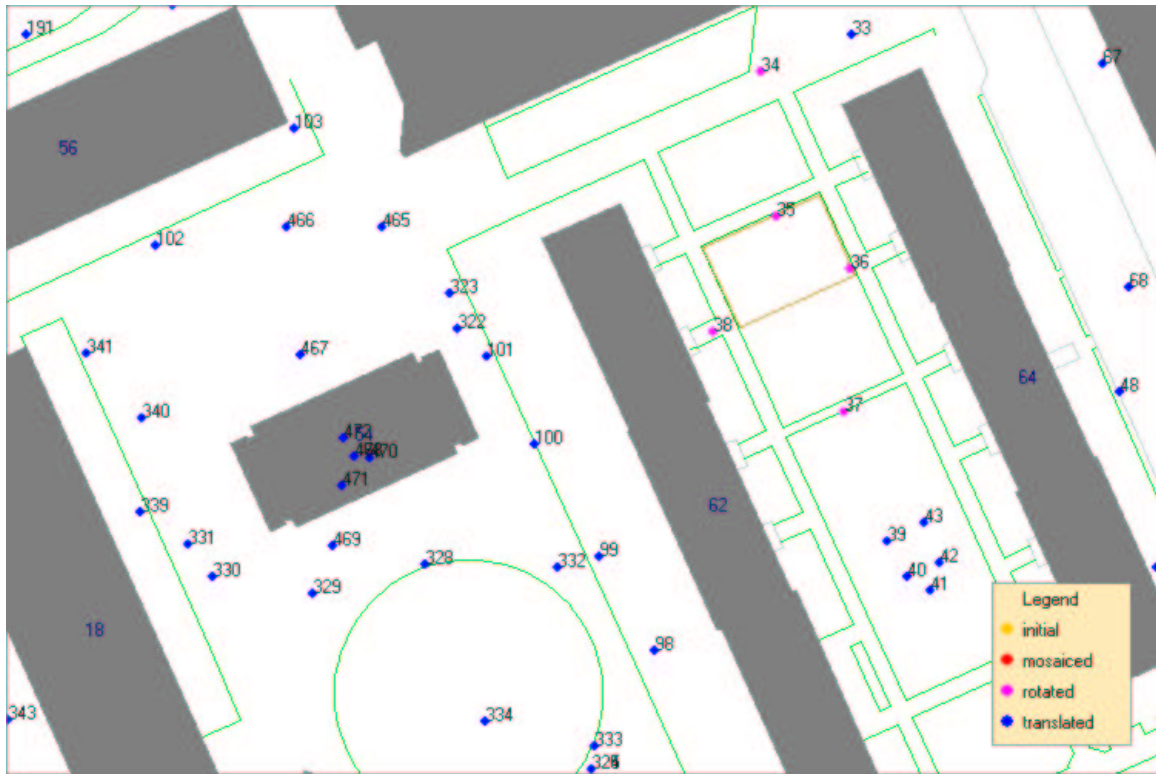

Figure 7-2: Screen shot of the Map Viewer zoomed in on the Green Building nodes
nodes won't clutter up the image.

7.1.2 Extensions to the Node Viewers

The Mosaic Viewer and Epipolar Viewer have been significantly upgraded. The most noticeable change to the user interface is the addition of the sphere viewport. This is a smaller window beneath the planar projection window which shows the unwrapped spherical texture¹. A screen shot of the Mosaic Viewer with the sphere viewport provided in Figure 7-3.

The sphere viewport allows the user to get some global context about where the mosaic viewer is looking by displaying a view of the entire sphere adjacent to the perspective from the node. As Figure 7-3 shows, the direction of the current view is indicated by a small gold target in the sphere viewport. This viewpoint target is

¹This a cylindrical projection that has been split lengthwise and unwrapped to make a flat 2D image.

Figure 7-3: The sphere viewport window

interactive. The user can drag and drop it to a new location in the viewport window and the view from the node perspective window will change accordingly. This makes locating objects that are visible in the unwrapped texture much easier and improves the overall experience of using the Mosaic Viewer and the Epipolar Viewer.

The Node Viewers Have a Heads-Up Display

The node viewers are more than just fancy image viewers. They are also equipped to make use of the pose data that accompanies each node in the City dataset. One thing that the node viewers can do with this information is provide the user with a heads-up display, as shown in Figure 7-4. In this image, the user has activated the heads-up display by clicking on a check box labeled “compass” directly beneath the mosaic viewer (not depicted). As the figure shows, the heads up display shows a gold target to denote the current viewpoint, as well as compass markings at the top of the window, which indicate the horizontal viewing direction in degrees, and hash marks

Figure 7-4: The heads-up display

along the left-hand side, which indicate the degrees of elevation.

The 0, 90, 180 and 270 degree hash marks for the compass heading are labeled with “N”, “E”, “S” and “W” respectively. By default, the node viewers always start with the viewpoint aimed at the direction of due North. This, in conjunction with the map viewer, which is oriented such that North is the vertical direction on the page, is meant to give the user some sense of direction while browsing the dataset.

Edge and Point Features Can Be Superimposed on the Node’s View

The node viewers have also been augmented with edge and point (i.e. edge intersection) visualizations, which can interactively display the features detected during the post-processing stages. The edge feature visualization can be activated by clicking on a check box beneath the node viewer which is labeled “edges”. The edges are displayed as purple lines superimposed on the viewing window which move along with the image as the viewpoint is rotated or zoomed. The intersections visualization is turned on by a check box labeled “intersections” and draws the point features as purple targets. Side-by-side screen shots of these visualizations are shown in Figure 7-5 (In the second view, both the edge and intersection visualizations have been activated for clarity).

Figure 7-5: Edge and Point Feature Display

The Epipolar Visualization Has Been Improved

The epipolar line drawing algorithm of the Epipolar Viewer has been meliorated for the new visualization suite. The old epipolar line algorithm projected a nearby point and a distant point on the same epipolar line and connected the two projected points to draw the epipolar line in the node's perspective window. The new algorithm begins at a point 1 meter distant from the source node and interpolates the epipolar line by incrementally plotting points farther and farther away from the node's eye. As the epipolar line heads off towards an infinitely distant vanishing point, one meter increments do not make much of a difference, $(\Delta X, \Delta Y)$, in the projected points, so the epipolar line algorithm increases the step size logarithmically by doubling it every time $\sqrt{(x_1 - x_0)^2 + (y_1 - y_0)^2} < 25$ pixels, where (x_0, y_0) are the projected coordinates of the previously drawn point and (x_1, y_1) are the coordinates of the current iteration. If the user has selected a check box labeled "scale", located beneath the viewing windows, hash marks perpendicular to the epipolar line labeled with the distance from the node's eye are drawn for each of the (x_i, y_i) sample points (see Figure 7-6), unless a maximum number of hash marks (30, in this implementation) have already been plotted. This prevents the epipolar line from becoming too crowded with tick marks near the vanishing point, when ΔX and ΔY become very small. At this point,

Figure 7-6: An epipolar viewing of Building 18 with distance markings on the epipoles

the step size also begins to increase by multiples of 10 instead of 2. The algorithm terminates when the step size passes a threshold value or a maximum number of iterations have been completed.

This algorithm is good because it is reasonably cheap, computationally speaking, and the simple heuristics for increasing the step size give the distance markings on the epipoles a nice, intuitive logarithmic scaling with integer distance values. Another alternative way to achieve uniform spacing of the distance markings in screen space would be to interpolate evenly in screen spacing while mapping the screen coordinates to epipolar coordinates using a technique borrowed from texture mapping:

$$t = t_1 + \frac{\frac{s}{z_2}}{\frac{1}{z_1} + s(\frac{1}{z_2} - \frac{1}{z_1})}(t_2 - t_1) \quad (7.1)$$

Here, s is a point on the (parametrized) projected line. $s = nd_s$, where n is the number of steps and d_s is the step size. t is the interpolated point on the parametrized

epipolar line, where the interpolation is between two points t_1 and t_2 , with corresponding z values z_1 and z_2 .² If t_1 is chosen such that the distance from the eye at this point is 0, then t is the distance from the eye at the interpolated point. The advantage of this approach is that the step size is always uniform in screen space, which saves computation where the previous algorithm would have to double the step size and try again when ever the screen step becomes too small. The disadvantage, however, is that screen space interpolation will generally not result in integer distance markings.

One additional modification to the Epipolar Viewer that would be fruitful, however, is to compute the vanishing point of the epipolar line, in order to accurately plot its ultimate endpoint. The vanishing point can never be reached by interpolation, since it is infinitely far away, so the epipolar lines plotted by the current algorithm terminate somewhat prematurely (though still at points much further than any objects in the images).

The vanishing point of an epipolar line is easy to compute, however, so it would not be difficult to modify the existing Epipolar Viewer to terminate epipolar lines at their vanishing points. The epipolar line, from the perspective of the source camera is given by the points along $\vec{r} = (xt, yt, t)$. This line projects to a point (x, y) in the view from the source camera. If the transformation between the orientations of the two cameras is given by the matrix M , then the equation of the epipolar line in the second camera's reference frame is:

$$\vec{r'} = M\vec{r} \quad (7.2)$$

M is a homogeneous matrix with a rotational and a translational component, so the transformed line will have the form $(a_1t + b_1, a_2t + b_2, a_3t + b_3)$, which, after applying the perspective transform looks like:

$$\left(\frac{a_1t + b_1}{a_3t + b_3}, \frac{a_2t + b_2}{a_3t + b_3} \right) \quad (7.3)$$

²In case the reader doesn't know, or needs a reminder, the parametric form of a line in three space is $\vec{r} = \vec{p}_1 + t\vec{p}_2$.

The vanishing point occurs where t is infinite, and is therefore $(a1/a3, a2/a3)$.³

7.1.3 New Global Visualizations

The extended interface also has some new global visualizations which work in both the Map Viewer and the node viewers. These allow the user to explore the vanishing points and baselines extracted during post-processing.

The Vanishing Points Visualization

If you’ve ever driven on I 80 through Death Valley, you are familiar with vanishing points. In any perspective projection, parallel lines in three-space, like the curbs of a highway, converge to a point in the projected image called the vanishing point. The rotational post-processing stage aligns nodes in the City Scanning Project Dataset by attempting to align vanishing points that are visible from a stereo pair of nodes. The vanishing points visualization is meant to show how well the rotation phase accomplishes this task by demonstrating how closely the vanishing points between two nodes are aligned relative to each other and how accurately the vanishing points line up with parallel lines in the real world.

Figure 7-7 shows a zoomed-in view of the vanishing points of the nodes along Massachusetts Ave., near MIT. The vanishing points are drawn as line segments with their midpoints at the location of the node in which they were detected. The length of these line segments, from the midpoint to one endpoint, is the distance between the source node and the source node’s furthest adjacent neighbor. This allows the alignment of the vanishing points between two adjacent nodes to be compared. If the two nodes are well registered rotationally, the vanishing points in the map viewer should appear to be parallel. Overlaying the vanishing points on the map of campus allows the user to see how they correspond to the physical geometry of the world. As

³Throughout this discussion I’ve used the perspective transformation for an ideal pinhole camera with unit focal length. This is valid for images in the City dataset because they are *undistorted* before entering post-processing in order to remove the radial distortion that is introduced by the real camera’s lens, making the pinhole projection mathematics applicable.

Figure 7-8: The node viewers' vanishing point visualization

sponding to the vertical edges of buildings) don't have much meaning in the planar projection of the Map Viewer. For this reason, the Map Viewer suppresses the display of any vanishing points that have an elevation of more than 45 degrees. The vanishing points visualization of the Map Viewer is activated by clicking a check box beneath the map which is labeled, "vanishing points".

The vanishing points are visible from the node viewers, as well. When a user activates the vanishing points visualization for a node viewer by selecting the "vanishing points" check box beneath the image windows, the node viewer displays a family of lines radiating from each vanishing point. To help the user find the source of the vanishing points, they are marked with stars in the sphere viewport window. Figure 7-8 shows the vanishing points of a node visualized using a node viewer.

Figure 7-9: The Map Viewer's baselines visualization

The Baselines Visualization

The other global features that are extracted by post-processing are baselines. Baseline directions in the City dataset closely match the directions between adjacent nodes. The Map Viewer's visualization of baselines is meant to show how accurate the correspondence between baseline directions and the actual directions between the nodes is. The Map Viewer draws baselines in a fashion that is analogous to the way it draws vanishing points, except that center point of a baseline line segment is located at the midpoint between two adjacent nodes. As it does for vanishing points, the Map Viewer matches the length of a baseline segment based to the distance between the two adjacent nodes which share it. Figure 7-9 shows the Map Viewer's baselines visualization. This visualization is turned on using a check box labeled "baselines" which is located underneath the map image.

The node viewers' allow the user to see the baseline directions from a node's perspective. When the baselines visualization for a node viewer is activated by checking the "baselines" check box beneath the image windows, the node viewer displays the

Figure 7-10: The node viewers' baselines visualization

baselines as blue cross-hair targets labeled with the corresponding node's ID number as shown in Figure 7-10.

7.1.4 The New Web Interface Has Support For Radiance Encoded Images

The pre-existing web interface displayed .jpg copies of the images in the City scanning dataset because most web browsers are not capable of decoding the .rgb image format that is used to encode images in the City dataset. This is no longer the case for the extended web interface, which is now equipped with a Java class for decoding and displaying images in the .rgb image format that can be plugged in to any of the visualization applets. This class is also capable of re-mapping the log radiance pixel values that are used in the City images to a linear scale.

The 0-255 scale of RGB color values in a standard image does not span a large enough range to fully capture all of the brightness values that are encoded in the high

dynamic range images in the City dataset. Instead, in the City images, the 0-255 color component values of a pixel are actually the log of the pixel's radiance value for each of the RGB color channels. The following formula is used to reconstruct a radiance value from its 0-255 log scale value:

$$R_c = e^{R_{min} + \frac{C_c(R_{max} - R_{min})}{255}} \quad (7.4)$$

In this formula, R_{min} and R_{max} are the minimum and maximum radiance values in the image, and C_c is the 0-255 log radiance value of the pixel to be re-mapped. When images encoded this way are displayed as is, they appear to be grayed-out or solarized. In order to correctly render the images, the log radiance pixel values must be re-mapped to a *linear* 0-255 scale, which is done using this formula:

$$L_c = \frac{R_c - R_{min}}{255 R_{threshold}(R_{max} - R_{min})} \quad (7.5)$$

The $R_{threshold}$ value is used to set a saturation threshold for the pixels. Pixels with radiance values greater than this will be assigned a value of 255 for the corresponding channel. If the results of Formula 7.1.4 are negative, the pixel is assigned a 0 value for channel c . The key to making log radiance encoded images look good on a computer display is to find the right value for $R_{threshold}$. The `.rgb` image class has a simple heuristic for doing this. It computes the cumulative distribution function for the radiance values in the image (for all channels) and sets the threshold to the radiance value at which the CDF is 90. This means that when the image is displayed, 90% of the pixels will be unsaturated. This is a pretty good heuristic for most cases, because most images only have a few really bright pixels from the sky while the rest of the image falls in a more limited dynamic range. All of the applets in the City Scanning Dataset web interface which display images are also equipped with slider bars that the user can manipulate to adjust the saturation threshold value.

The source code for the `.rgb` radiance-encoded image class and an `.rgb` image

viewing applet can be downloaded from the City Scanning Project Dataset web site.⁴ More information on the .rgb image format can be found in [Haeberli, 2002], and the reader can learn more about radiance from [Horn, 1986].

7.2 Content Handlers Can Perform Data Caching

The DataLink Server makes it possible to cache some data that is accessed frequently, but is slow to generate. A couple of examples of this behavior exist on the “browse” page. This page is the first navigation vertex that the user will traverse when accessing the dataset. It brings up the Map Viewer of campus and plots the locations of all of the nodes in the dataset, color-coded according to state of post-processing refinement. The information about node locations comes from the camera file of image 0 for each of the nodes. This means that, without some kind of caching, the DataLink Server has to retrieve each of the image 0 camera files individually, open them and extract the pose data. This is a very slow process because the number of these camera files is very large.

The bottleneck that comes from retrieving and opening a large number of files like this is not the DataLink Server. The problem is actually the overhead that comes from making so many HTTP protocol request to open the files. Caching can be used to cut down on this overhead significantly by packing all of the node location data into one file, and then serving only this file to the applications that request location information for a large number of nodes in the dataset. The applications are then responsible for parsing the node locations file to extract the data that they need.

Caching can be implemented fairly easily using the DataLink Server. For node locations it is done by creating a special node locations navigation vertex. The content handler for this vertex is simply a special servlet which serves the cached node locations file to the client application when this file is up-to-date. When the cache file is not up-to-date, this servlet is responsible for regenerating it, which is done by making recursive requests to the DataLink Server to retrieve and open the node 0

⁴[<http://city.lcs.mit.edu:8080/data2/open_source/rgb/>](http://city.lcs.mit.edu:8080/data2/open_source/rgb/)

camera files for each node.

To implement a caching content handler like this is not difficult. The only requirement, in terms of the DataLink Server configuration, is that the navigation vertex to which the caching content handler is affixed must have a child vertex for data files which are used to generate the cached data. The caching content handler simply checks the time stamps of each of the branches of this vertex, when it receives a request, to see whether the cache is up-to-date. The way that the caching content handler determines whether the cache is up-to-date with the data is by first checking that all of the branches have earlier timestamps than the cache file. This is a quick way of checking whether any of the source files have been modified, or whether new ones have been added, but it will not be able to detect changes in the names of symbolic links or whether source files have been deleted. To detect these changes the caching content handler computes a checksum from the size, t_i , of each of the branches and their names, s_i , according to this formula:

$$S = \sum_{i=0}^N t_i \bmod \text{hashcode}(s_i) \quad (7.6)$$

This checksum is compared against the checksum of the cached file, and if they match, the cached file is served. Otherwise, it is regenerated and then served. The combined use of the branch name and size captures all of the possible changes that occur to the data. It is not foolproof, though. Some changes may not be detected if there is a hash code collision for two different files of the same size or if both the new name and the old name of a renamed file generate hash codes that are less than the file size. However, since most changes to the data involve adding a group of nodes or re-numbering all the nodes, this hash code strategy should detect most changes in conjunction with the time stamps check.

This caching strategy has been employed for the node locations data, as well as the baselines data used by the Map Viewer on the “browse” page of the extended web interface. It dramatically speeds up the operation of this part of the web portal when these data are accessed. A similar caching strategy could also be applied to the

vanishing points data used on the same page.

7.3 User Auditing and Debugging

In order to keep tabs on the usage of the web interface, as well as to help identify problems with it, I have set up a user auditing system which logs the IP address of each client that accesses the web interface combined with information about what resource, servlet, JSP or HTML document they requested. This information is stored to the Tomcat servlet container's log file for the City data webapp.

I have also created another pair of remote auditing and debugging tools: the `MonitorServlet` and the `OutputStreamServer`. These tools attack one of the major difficulties associated with developing JSPs and Java servlets: These applications run on a remote server, which makes them difficult to debug. Many times a developer would simply like to output some `printf` (or in this case `System.out.println`) statements to the console in order to get an idea of the buggy program's behavior. These statements will simply be redirected to some console on the remote server however, and the developer will never be able to see them.

The `OutputStreamServer` solves this problem by allowing a developer to redirect one or more of the standard output streams to a simple server that forwards anything output to the stream to a remote client via a TCP/IP connection. It is also possible to redirect a non-standard output stream to the `OutputStreamServer`, which makes it possible to use the `OutputStreamServer` as some kind of remote logging utility. Any number of clients can connect to the `OutputStreamServer`, which maintains a table of all connections to it, and the `OutputStreamServer` is thread safe.

To use the `OutputStreamServer` for debugging JSPs and servlets, I have created another simple servlet called the `MonitorServlet`. The `MonitorServlet` runs in the same webapp as the servlets and JSPs to debug, and presents the user with the CGI form shown in Figure 7-11. This form provides some controls for starting and stopping an `OutputStreamServer` and, when requested, redirects the standard out and standard error streams of the virtual machine in which it is running

Servlet and JSP Monitor

[Connect to monitor server.](#)

Test URL:

Port:

Figure 7-11: The `MonitorServlet`

to the `OutputStreamServer`. All of the JSPs and servlets in the same webapp as the `MonitorServlet` will share the same virtual machine, and, therefore, this redirection of the output stream will affect all of them, as well. To test out one of the servlets or JSPs, the developer just connects to the `OutputStreamServer` by clicking on the “Connect to monitor server” link, which opens a telnet connection to the `OutputStreamServer` automatically on the specified port.⁵ Then the developer types the URL into the form and presses “go” and the `MonitorServlet` forwards the developer to the specified servlet or JSP. The developer can then interact with the JSP or servlet as they normally would, via the web browser, and any debug messages in the code will be redirected to a console on the developer’s machine via the `OutputStreamServer`.

As mentioned earlier, a single `OutputStreamServer` will accept multiple connections. The `MonitorServlet` will only allow the developer to start one `OutputStreamServer` on the remote machine at a time. This is to prevent multiple, unaccounted for `OutputStreamServer` instances from accumulating on the server and wasting resources. The `OutputStreamServer` periodically updates a shared variable which the `MonitorServlet` uses to check whether it is alive, so it would be uncomplicated to extend the system to support multiple `OutputStreamServers` which could be remotely maintained by the `MonitorServlet`. The source code for both of these tools is located in Appendix D.

⁵The City server will only accept connections from within the Graphics Group domain.

Chapter 8

Contributions and Concluding Remarks

The principle contributions of this thesis are the DataLink Server, a scaleable, modular and customizable tool for building web interfaces to large datasets, which automatically provides navigation and data retrieval infrastructure; and the Geospatial Coordinate Transformation Library, which provides static C++ library routines for performing nearly any coordinate transformation involving points on the Earth or geographic maps. These utilities have been used to build a powerful web interface to the City Scanning Project Dataset, the largest collection of geospatial imagery in existence, which exposes the data to anyone on the web, including our colleagues in the field of machine vision. 3D and 2D visualizations, including the Map Viewer, the Mosaic Viewer and the Epipolar viewer are used throughout the web interface to present the data in both a pedagogical and utilitarian way.

Briefly, some high level contributions related to the DataLink Server are:

- The DataLink Server provides an easily configurable abstraction between a physical data hierarchy, such as a directory structure or a database, and a set of virtual navigation hierarchies.
- Content handlers create a way to embellish the web interface produced by the DataLink Server with a modular and customizable front end.

- The XML modeling language for configuring the DataLink Server is a descriptive and comprehensible language for describing data hierarchies and directing navigation through large datasets.

A short list of the services purveyed by the Geospatial Coordinate Transformation Library is:

- A universal tool for writing programs involving precise coordinate transformations of geographic coordinates, including geocentric, geodetic and cartographic conversions
- An extensible API that makes coordinate types and reference frames explicit
- A teleological naming convention that makes mastering the techniques for manipulating geospatial coordinates facile

I have also contributed the following web visualizations for exploring the City Scanning Project Dataset online:

- A Map Viewer which superimposes the refined location estimates of the nodes in the City dataset for the first time ever on a CAD map surveyed using conventional techniques that demonstrates the precision of the City Scanning Group's 3D reconstruction algorithms
- Visualizations of edge and point features, vanishing points and baselines in the City dataset
- An Epipolar Viewer for comparing the quality of registration of stereo geospatial image pairs

It is my hope that the visualizations I have created will prove to be an informative educational tool for other researchers in the field of machine vision, or curious web surfers, who would like an opportunity to learn more about the City Scanning Project. These tools should also turn out to be an effective way for members of the City Scanning team itself to validate and evaluate the image processing and machine vision

algorithms being developed as part of the City Scanning Project. Lastly, I believe that the DataLink Server and the Geospacial Coordinate Transformation Library themselves will provide powerful utilities for the software development community at MIT and beyond to create web portals to large datasets and work with geospatial coordinate systems.

Appendix D

Source Code For the OutputStreamServer and MonitorServlet

D.1 OutputStreamServer.java

```
package util.monitor;

import java.io.*;
import java.net.*;
import java.util.*;

/**
 * Debugging JSPs and servlets can be a real pain because they
 * execute on the remote server within the servlet engine. Even if
 * the servlet engine elects to output any System.out.println
 * messages they probably just get printed to a console window on
 * the server, which is no good to somebody logged in on a
 * development machine. I wrote this simple server class to get
 * around that issue. It allows clients to login to a specified port
 * (using telnet or a similar client interface) to receive data sent
 * to the OutputStreamServer. OutputStreamServer extends
 * OutputStream which makes it possible to redirect standard out or
 * standard error to an OutputStreamServer. This lets a developer
 * insert System.out.println debug statements in his/her servlet code

```

```

* and see them printed in a console window at a development machine.
*
